Abstract

Among the elements that constitute the solid surface of the earth, magnesium (Mg) is the eighth most abundant and an essential plant nutrient. Mg, the central component of chlorophyll, plays a major role in plant nutrition. Although Mg is regarded as a macronutrient, it is not always considered in fertilizer management possibly because Mg is added to soil as an accessory element in many fertilizers. Increasing incidences of Mg deficiency are being observed mainly as a result of the use of Mg-free fertilizers. Furthermore, modern agricultural practices are inducing accelerated soil acidification. If uncorrected, this acidification will lead to a reduction in exchangeable basic nutrient cations, leading to the increasing incidence of Mg deficiency in soils. The role of Mg in plants and animals is discussed in relation to the supply of Mg in soils.

MAGNESIUM (Mg) IN SOILS

Mg is a normal component of both igneous and sedimentary rocks and the soils developed from such rocks.^[1] Soils developed from basic rocks (basalts and limestone) generally contain higher levels of Mg (0.27–2.86% Mg) than those developed from granite and sandstones (0.01–0.34% Mg).^[2] The bulk of Mg in soil is usually in forms that are not readily available to the plant and exists in primary minerals and secondary silicate clay minerals.^[3] Some of the important silicate mineral species carrying Mg are shown in [Table 1](#). The formulas presented represent the “ideal” composition of the minerals. In nature, however, the composition varies, depending on the extent to which elements substitute for each other in the crystalline structure of these mineral species.

Soil Mg is often subdivided into soluble, rapidly exchangeable, slowly exchangeable, and structural (mineral) forms.^[4] These arbitrary subdivisions account for differences in bioavailability.^[5] The availability of Mg in soils for plant uptake is as follows: solution > exchangeable > mineral. There is an equilibrium between the forms of Mg that allows the release of Mg from less-available forms to the more-available forms. Only a small fraction of the total Mg is present in soil solution,

and plants absorb Mg from soil solution, which is buffered by the readily exchangeable forms.

Most soils hold important reserves of Mg in primary and secondary minerals.^[5,6] These reserves contribute a large proportion of the Mg needs of annual and perennial crops.^[7] The rate of release of Mg for plant uptake depends on the rate of weathering of these minerals. Studies on the kinetics of Mg release from soils and soil fractions using cation exchange resins, dilute salts, and organic acids showed that as weathering proceeds, the slowly exchangeable Mg originates from progressively coarser particle-size fractions.^[8] The rate of release of slowly exchangeable Mg increases with a decrease in particle size. Further, the presence of surface coatings on a mineral surface acts as a semipermeable barrier, reducing the rate of mineral weathering and, consequently, the rate of Mg release to soil solution.^[9]

Mg IN PLANTS

Mg forms the central unit of chlorophyll in plant leaves and cannot be substituted by other metals. Mg is involved in the production of starch during photosynthesis. Because Mg is a component of chlorophyll, an insufficient supply reduces chlorophyll formation, which

Table 1 Mg minerals in soils.

Mg minerals	Chemical formula	Mg content (g Mg/kg)
Forsterite	Mg ₂ SiO ₄	320–350
Pyrope	3MgO · Al ₂ O ₃ · 3SiO ₂	60–130
Iolite	H ₂ (Mg, Fe) ₄ Al ₈ Si ₁₀ O ₃₇	50–80
Diopside	CaMg(SiO ₃) ₂	20–140
Augite	CaMg(SiO ₃) ₂	45–100
Enstatite	MgSiO ₃	180–220
Actinolite	Ca(Mg, Fe) ₃ Si ₄ O ₁₂	100–160
Hornblende	CaMg metasilicate	10–90
Serpentine	H ₄ Mg ₃ Si ₂ O ₉	19–26
Talc	H ₂ Mg ₃ Si ₄ O ₁₂	160–200
Phlogopite	H ₃ Mg ₃ Al(SiO ₄) ₃	130–180
Biotite	(H,K) ₂ (Mg, Fe) ₂ Al ₂ Si ₃ O ₁₂	10–160
Clinochlore	H ₈ (Mg, Fe) ₅ Al ₂ Si ₃ O ₁₈	100–120

Source: Adapted from Beeson.^[2]

is likely to affect the photosynthetic ability of the plants. Mg has a controlling action on the swelling of plasma and plays a major role in many enzyme functions in plants.^[10]

Mg deficiency symptoms generally show up rather clearly in plant leaves, and Mg is readily mobile in plants. It moves from the older leaves to the younger leaves when Mg is deficient, and the deficiency symptoms therefore show first on the older leaves as Mg is withdrawn from them. The deficiency is initially characterized by an interveinal chlorosis; although in acute stages, the leaf may be generally deficient in both green and yellow pigments (variegated coloration), and necrosis may occur in the areas of the leaf first affected by Mg deficiency. A deficiency of Mg also induces the formation of anthocyanins in some plant species, such as cotton (*Gossypium hirsutum*). Economically, one of the most important Mg deficiency diseases is identified in tobacco (*Solanum tobaccum*), commonly referred to as “sand drown.” This occurs when tobacco leaves contain less than 0.25% Mg on a dry-weight basis. Similarly, Mg deficiency in pasture leads to “grass tetany” in grazing animals. The deficiency of Mg in pasture occurs when the concentration is less than approximately 0.2%.^[11]

Mg deficiency in plants generally occurs in soils that are low in exchangeable Mg, light textured, highly leached, acidic, and low in cation exchange capacity (CEC).^[12] In addition, induced deficiency may occur on some soils as a result of nutrient imbalances. Soils that are heavily fertilized, particularly with materials lacking in Mg or high in calcium (Ca), potassium (K), and methane (NH₄), can also induce Mg deficiency.^[13] By growing crops that require high levels of Mg

throughout the growing season (e.g., tobacco), Mg deficiency in soils may be exacerbated.^[12,14]

Mg IN ANIMALS

Mg plays an important role in the enzymatic metabolism of carbohydrates, lipids, proteins, and nucleic acids. Generally, Mg is an activator for numerous enzymes, such as phosphatases. It is also involved in the nerve conduction and muscular contraction.

Deficiency of Mg in blood plasma causes a disorder known as hypomagnesemia (grass tetany or staggers), which usually occurs in dairy cows in the early part of lactation.^[15] Mg deficiency in animals can be overcome by the regular use of Mg salts as drench or water trough treatment, as a lick, or in pasture after foliar application.

The application of excessive amounts of K fertilizer and K-rich farm effluents has been shown to increase the incidence of Mg deficiency leading to grass stagger. In pasture and fodder crops, grass stagger index (GSI; Eq. 1) is used to predict the occurrence of Mg deficiency.

$$\text{GSI} = [\text{K}^+]/([\text{Ca}^{2+}] + [\text{Mg}^{2+}]) \quad (1)$$

where $[\text{K}^+, \text{Ca}^{2+}, \text{Mg}^{2+}]$ = milliequivalents/kg-DM.

It has been suggested that GSI values in the pasture in excess of 2.2 enhance the risk of grass stagger development. This condition is generally linked with animal serum Mg levels less than 1.0–1.5 mg/100 ml, compared with normal levels in cattle of 1.7–3.0 mg/100 ml. This condition arises in response to diets low in Mg- or K-induced inhibition of Mg absorption in the rumen.^[15]

Mg FERTILIZERS

Mg deficiency in soils can be overcome by adding Mg-containing compounds (Table 2).^[16] Epsom salt (MgSO₄) is soluble in water and used as a fast-release Mg source. Other fertilizers are insoluble in water and are used as a slow-release source. The manufacture and use of serpentine superphosphate as a fertilizer material are declining. Dolomite, which contains both Ca and Mg, is more effective in acidic soils because the Mg is brought into solution by the acidic soil. Dolomite is the most widely used source of Mg, both as an ingredient of mixed fertilizers and as a separate amendment for liming.

All the slightly soluble Mg fertilizers listed in Table 2 are acid-neutralizing materials and would thus reduce the acid-forming potential of the fertilizer to which they might be added. Mg silicates, including magnesites, are ineffective sources of Mg for plants. Selectively calcined dolomite, in which the Mg component is oxidized to MgO, is more reactive than dolomite. Calcined magnesite can be added to soils or dusted onto pasture as a source of Mg.

Table 2 Mg fertilizers.

Mg minerals	Chemical formula	Mg solubility (mmol/liter)	Solubility product (pK _{SP})	Mg content (g Mg/kg)
Dolomite	MgCO ₃ · CaCO ₃	0.038	17.09	100
Calcined dolomite	MgO · CaCO ₃			160
Hydrated dolomite	MgO · Ca(OH) ₂			170
Magnesite	MgCO ₃	0.076	8.24	260
Brucite	Mg(OH) ₂	0.091	11.41	360
Magnesia	MgO	0.150		560
Kieserite	MgSO ₄ · H ₂ O	4,943		160
Epsom salt	MgSO ₄ · 7H ₂ O	127.3		90
Kainite	MgSO ₄ · KCl · 3H ₂ O			70
Langbeinite	2MgSO ₄ · K ₂ SO ₄			110
Forsterite	Mg ₂ SiO ₄	0.067 × 10 ⁻³	28.11	320–350

FACTORS AFFECTING Mg AVAILABILITY TO PLANTS

Plants differ markedly in their response to Mg deficiency in soil. The input and losses of Mg, forms of Mg in soils, and the interaction of Mg with other cations are some of the important properties affecting the plant availability of Mg.^[17] Mg concentration in plants is depressed by high concentrations of other cations, such as Ca, K, NH₄, and aluminum.^[18] Field trials have indicated that continuous use of ammonium-based fertilizers such as diammonium phosphate along with muriate of potash (KCl) results in Mg deficiency in pasture.^[11] The addition of KCl decreases the concentration of exchangeable Mg in soils, which is attributed mainly to the displacement of Mg by K ions added through the fertilizer.

Lime-induced reductions in tissue Mg level and Mg uptake by plants have been observed by a number of researchers.^[19] This effect occurs following an increase in Mg adsorption resulting from an increase in pH-dependent adsorption sites in soils containing variable charge components. Liming has also been shown to increase the leaching potential of Mg mainly because the Ca added through lime exchanges with Mg on the soil surfaces leading to the leaching of Mg in soil solution.^[20]

A number of soil test methods are used to predict Mg availability to plants, including 1N NH₄OAc-exchangeable Mg, percentage CEC saturated with Mg, and indexes of relative Mg concentration in soil solution (pMg in soil solution, pMg–pCa in solution, and half pMg–pK in solution).^[21] The ability of these indexes to predict the

availability of Mg to plants varies depending on the relative concentration of Mg, Ca, and K in soil solution.^[22] Field calibrations for the Mg soil test are available that enable the soil testing service to predict the Mg status of the soils and to make necessary Mg fertilizer recommendations.

CONCLUSION

As the central unit of chlorophyll, Mg is one of the most important plant nutrients. Mg is usually added as an accessory element along with other fertilizer materials. Plants take up Mg from soil solution, which is replenished through the continuous release from the exchange sites. Epsom salt is one of the most important soluble Mg sources added as a fertilizer material. Dolomite is a sparingly soluble material and is used extensively both as a source of Mg and as a liming material.

Excessive amounts of K in fertilizers and farm effluents generally decrease the uptake of basic cations, especially Ca and Mg by pasture. This is mainly the result of depletion of these cations in soil solution that results from leaching because of the competition from K ions for the cation exchange sites of the soil. To reduce the deficiency of Mg in grazing animals, it is important that this nutrient is added to soils, which receive regular effluent irrigation or K fertilizer application.

The timing of the application of K-based fertilizers to pasture soils is important in regulating the supply of Mg for dairy cattle. Increased Mg requirements at the end of pregnancy and in early lactation periods need to be supplemented by drenching with Mg salts. The Mg requirement of dairy cattle can be regulated by adjusting the dietary cation–anion balance (DCAB). An acid DCAB in the animal ration is likely to overcome grass tetany disorders in dairy cattle caused by Mg deficiency.

Manganese: Brazilian Soils

Diego Antonio França de Freitas

Nilton Curi

Federal University of Lavras, Lavras, Brazil

Nestor Kämpf

Federal University of Rio Grande do Sul, Porto Alegre, Brazil

Abstract

Manganese (Mn) content in Brazilian soils is extremely varied, ranging from very low values in soils derived from sandstone up to extremely high values in soils derived from ferruginous dolomite. This variability is also related to the environmental conditions, highlighting the soil drainage because although Mn is insoluble under oxidizing conditions, it is soluble under reducing conditions. The peculiar Mn behavior in Brazilian soils impact cropping systems and the environment, mainly due to the high sorption of Mn and consequently large accumulation capacity of trace elements.

INTRODUCTION

Manganese (Mn) oxides generally occur in small proportions in parent rocks and soils; however, they have significant influence on their chemical properties and show high sorption capacity of trace elements and therefore are able to accumulate large amounts of these trace element ions. Mn is also necessary for human and plant health in small quantities.

The majority of Brazilian soils have concentrations of Mn near the world average.^[1] However, due to the environmental variability of Brazilian soils, related to the parent material and environmental conditions, mainly soil drainage (Mn is sensitive to reduction–oxidation reactions), a wide variability of Mn values ranging from very low to extremely high, impacting cropping systems and the environment, is found.

Mn IN SOILS

Mn oxides commonly have authigenic origin in soils and are formed by chemical or biochemical precipitation from the solution and by crystallization of dispersed colloids.^[2] In soils presenting oxidizing pedoenvironments (well-drained soils), Mn content is generally related to the parent materials (normally associated to iron oxides); Mn tends to occur disseminated in the soil as finely dispersed particles, with higher concentrations in the A horizon (through biocycling) and in the C horizon (through accumulation). In soils having variable oxidizing–reducing environments (imperfectly to poorly

drained soils), higher Mn contents occur in the form of discontinuous (black and brown) coatings (mangans) on the surface of aggregates or filling the pores, forming concretions and nodules, generally situated in the zone where the water table fluctuates. However, the accumulation of Mn in soils does not necessarily indicate the redox environment, as they may be relicts of preterit wetter conditions.^[2] In the form of mangans, Mn^{4+} (oxidized form) can be easily reduced to Mn^{2+} (reduced form) and cause toxicity to plants, considering the latter is mobile in soils solution. It is worthy to mention this reduction (gain of electrons) is frequently accelerated by microorganisms.

In the acid soils (pH 4–5), the contents of soluble Mn generally reach toxic levels for crops, primarily in soybeans [*Glycine max* (L.) Merr], which may be neutralized by the addition of lime. In soils with high Mn contents and without apparent evidence of Mn toxicity, prolonged periods of water residence time in the rainy periods can favor the dissolution of oxides by reduction, temporarily releasing soluble Mn in toxic levels to sensitive plants.

In soils, the occurrence and formation of Mn oxides are influenced by the higher proportion of different ions, microorganisms, and organic compounds contributing to their small particle size, high surface area, and low crystallinity.^[2] Mineralogical characterization of the Mn oxides in soils is a challenge due to the large number of minerals, inaccurate knowledge of some of their structures, the diffuse nature of X-ray diffraction (XRD) patterns of some minerals, and the coincidence of reflections with other associated minerals.

Mn IN BRAZILIAN SOILS

Brazilian soils have a wide range of total content of Mn (Table 1). Thus, very low contents were recorded in Quartzarenic Neosols (Psamments) derived from sandy sediments of Southeastern Brazil, São Paulo State.^[6] This parent material generates mostly sandy soils, with low organic matter contents, which have a low capacity to retain Mn. Also, these soils are low in weatherable minerals and do not have a source for Mn. In soils of Rio Grande do Sul State, Southern Brazil, the highest contents of Mn were found in Latosols (Oxisols) originating from basalt.

In the Cerrado region of the Central Plateau of Brazil, soils are, in general, highly weathered, leached, and acidic, with small amounts of available nutrients for plant growth. In this region, where Latosols (Oxisols) cover 47% of the Cerrado biome, particularly in the highlands, Mn toxicity is more frequent than deficient due to the high soil acidity. In the sandy soils of this region, which are naturally low in Mn, there is commonly a deficiency of available Mn to crops. The highest values of Mn were found in soils developed from basalt in this region. According to Marques et al.^[9] due to the long weathering–leaching process that these soils had undergone, the average concentration of total Mn found, i.e., 216 mg kg⁻¹ in soils developed from sedimentary deposits, is equivalent to half of the world average, 558 mg kg⁻¹.

However, the highest Mn contents in the world were reported, especially in perferric soils derived from ferruginous dolomite in the Environmental Protection Area of Belo Horizonte city (APA Sul RMBH), a representative area of the Iron Ore Province, covering 1625.32 km², located between the coordinates 19°55′–20°15′S and 42°55′–44°15′ WGR (Fig. 1), Minas Gerais state: extreme values of 35,882 mg Mn kg⁻¹ of soil by sulfuric acid digestion,^[11] 73,000 mg Mn kg⁻¹ of soil by triacid digestion,^[12] 84,033 mg Mn kg⁻¹ of clay by sodium dithionite-citrate-bicarbonate,^[13] and 33,728 mg Mn kg⁻¹ of clay by acid ammonium oxalate.^[10] In these Mn-rich soils, the influence of the parent material is stronger than the soil landscape position and the degree of weathering–leaching of these soils. Due to their high content of Mn, these soils from the Iron Ore Province are a natural base for a variety of studies, ranging from basic research to environmental sustainability, as suggested for South Africa.^[14]

When compared to soils from temperate regions, Brazilian soils generally have higher Mn contents. The environmental conditions have created systems with acidic pH, high oxidation of organic matter, oxidation–reduction, and weathering, presenting a typical situation in which hardly reducible forms of Mn contribute significantly to the more available forms of Mn.^[5]

Identification data of Mn minerals in Brazilian soils are rare. In soils from the State of Rio Grande do Sul, Mn

Fig. 1 Geographic location of APA Sul RMBH, Iron Ore Province, Minas Gerais State, Brazil.

Source: From Carvalho Filho, Curi, et al.^[10]

oxides were identified by XRD in 6 out of 12 samples of nodules and mangans, following concentration pretreatments, and birnessite was the most frequently found Mn oxide.^[15] Due to the peculiar Mn-rich nature of soils from the Iron Ore Province, Minas Gerais State, todorokite, lithiophorite, and pyrolusite were identified by XRD in the clay fraction of soils without any concentration pretreatments.^[10]

CONCLUSION

Brazilian soils have a wide range of Mn contents with some of the lowest to some of the highest values in the world. The variability is primarily related to the parent material from which the soils were formed. The climate and soil environment also provide more variability. Some soils in Brazil are affected by seasonal water tables, which impact the vertical distribution of Mn. Under oxidizing conditions, Mn is insoluble but it is soluble under reducing conditions. Additionally, phytocycling alters the vertical distribution of Mn. Commonly, some of the highest contents of Mn in a soil profile occur in the upper horizon. When soils are cultivated, Mn deficiencies may appear in well-drained sandy soils. Conversely, Mn in

some acidic soils may be toxic to sensitive crops. The wide range of Mn contents in Brazilian soils is related to the parent material and environmental conditions, mainly soil drainage.

Abstract

Livestock contributes both directly and indirectly to climate change through the emissions of greenhouse gases (GHGs) such as carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O). Animal manure and its use as fertilizer contribute to gaseous emissions. CH₄ and N₂O are the two major GHGs produced from livestock manure, which has a direct impact on global warming. CH₄ emissions from manure storage globally was estimated to be 470 Mt CO₂e/yr in 2010 with an expected 11% increase by 2020, and N₂O emissions from fertilizer use, manure application, and deposition by grazing livestock was estimated at 2482 Mt CO₂e/yr in 2010 with an expected 18% increase by 2020. Besides these, other emissions from livestock manure management systems are ammonia, nitric oxide, and non-CH₄ volatile organic compounds. The nature of the nitrogen cycle and its interaction with the carbon cycle demands a holistic approach for addressing gaseous emissions and mitigation research by developing suitable abatement strategies from manure management. Most representative and management technology combined with data for the specific area or region must be considered to obtain reliable results.

INTRODUCTION

The major source of gaseous emissions from livestock production sites is the waste or manure in solid, slurry, or liquid forms, with diverse physical properties. Once excreted, processes of biological decomposition and formation of gaseous compounds continue but diminish as manure cools and dries. Animal manure and its use as fertilizer contribute to gaseous emissions. Manure contains complex organic compounds (e.g., carbohydrates and proteins), which are broken down by bacteria resulting in the production of carbon dioxide (CO₂) under aerobic and methane (CH₄) under anaerobic conditions. With open grazing, manure is spread thinly, and aerobic decomposition predominates. In intensive livestock practices, animals are housed or kept in confined spaces for part of the year, and manure is concentrated and stored in tanks, lagoons, or pits where anaerobic conditions predominate and CH₄ is

produced. Bacteria, archaea, and other groups are also involved in microbial activities taking place during manure storage. Thus, manure is a source of greenhouse gas (GHG) emissions due to a multitude of microbial activities. These GHG emissions contribute to radiative forcing, which ultimately add to global warming. Besides these GHGs, other emissions from livestock manure management systems are ammonia (NH₃), nitric oxide (NO), and non-CH₄ volatile organic compounds (NMVOCs). This entry collates and synthesizes information pertaining to GHG emissions from livestock manure and its abatement strategies.

SIGNIFICANCE OF LIVESTOCK MANURE FOR GLOBAL WARMING

Increased emission of GHG has drawn worldwide attention due to risks of global warming and stratospheric ozone

depletion. Livestock contribute both directly and indirectly to climate change through the emissions of GHGs [e.g., CO₂, CH₄, and nitrous oxide (N₂O)]. Globally, the livestock industry contributes 18% (7.1 billion tons CO₂ equivalent) of global GHG emissions. Although it accounts for only 9% of global CO₂, it generates 65% of human-related N₂O and 35% of CH₄, which has 298 times and 25 times the global warming potential of CO₂, respectively. Much of the global GHG emissions from agriculture sector arise from enteric fermentation and manure from grazing animals. Animal wastes contain organic compounds such as carbohydrates and proteins. During the decomposition of livestock wastes under moist, oxygen (O₂)-free (anaerobic) environments, anaerobic bacteria transform the biomass carbon (C) into CH₄. Animal wastes also contain nitrogen (N) in the form of some complex compounds. The microbial processes of nitrification and denitrification of animal waste form N₂O, which is emitted to the atmosphere. CH₄ emissions from manure storage globally are estimated to be 470 Mt CO₂e/yr in 2010 with an expected 11% increase by 2020, and N₂O emissions from fertilizer use, manure application, and deposition by grazing livestock are estimated at 2482 Mt CO₂e/yr in 2010 with an expected 18% increase by 2020.^[1] Chianese et al.^[2] reported average CH₄ emissions from covered slurry, uncovered slurry, and stacked manure to be 6.5, 5.4, and 2.3 kg/m²/yr, respectively, although rates vary with temperature and time of storage. N₂O emissions from soil application of manure are a major contributor to total GHG emissions from agriculture with animal waste representing 30–50% of the global agricultural emissions. [Table 1](#) describes the amount of manure produced annually by different species of livestock.

FACTORS INFLUENCING MANURE GAS PRODUCTION

Principal factors that affect gaseous emissions from manure include temperature, O₂ level (aeration), moisture, and sources of nutrients. These factors are affected, in turn, by manure type (livestock type), diet, storage, and handling (pile, anaerobic lagoon, pit, etc.), and application of manure (injected, incorporated, etc.). These emissions arise from

the excreta of livestock deposited in and around buildings and from manure stores following land spreading of manures and collected as liquid slurry, solid manure, or litter-based farmyard manure (FYM). Relative importance of these emissions depends not only on manure composition and local management practices with respect to treatment, storage, and field application but also on ambient climatic conditions. The specific factors influencing each gas production are discussed below.

DIFFERENT GASES PRODUCED FROM LIVESTOCK MANURE

Important gases produced from livestock manure with direct and indirect impacts on global warming are discussed below.

Methane

The term “manure” is used here collectively to include both dung and urine (i.e., the solids and the liquids) produced by livestock. Besides enteric CH₄ production, manure storage is also a source of CH₄, especially in liquid form as slurry or compacted form, and the magnitude of CH₄ production depends on storage conditions and anaerobic decomposition of organic matter. Enteric fermentation from dairy cattle usually accounts for 80% of CH₄ with manure contributing about 20%. Methanogenesis occurs only under strict anaerobic conditions where it is coupled to other processes involved in the breakdown of manure organic matter. These conditions occur most readily when large numbers of animals are managed in a confined area (e.g., dairy farms, beef feedlots, and swine and poultry farms) and where manure is disposed of in liquid-based systems. Principal factors affecting CH₄ emissions from manure are the amount of manure produced and the portion of the manure that decomposes anaerobically. The former depends on the rate of waste production per animal, number of animals, feed intake, and digestibility, and the latter depends on how the manure is managed (e.g., whether it is stored as liquid or spread as solid). When manure is stored or treated as a liquid (e.g., in lagoons, ponds, tanks, or pits), it decomposes anaerobically and can produce a significant quantity of CH₄. The CH₄ conversion factor (MCF) for different sources of manure is described in [Table 2](#). The temperature and the retention time of the storage unit greatly affect the amount of CH₄ produced. The CH₄-producing potential of the manure varies by animal type ([Table 3](#)) and the quality of the feed consumed. For example, slurry from swine emits more GHG than that from cattle.^[3] Long-term storage of manure at high temperature promotes biological activity, thereby enhancing CH₄ production. In humid climates, air is excluded, soils become anaerobic, along with increase in the potential for CH₄ production.

Table 1 Amount of manure produced annually per kg live weight.

Animal	Solids (kg)	Urine (kg)	Total wet weight (kg)	Total dry matter (kg)
Horse	14.4	3.6	18	4
Chicken	8.4	0	8.4	4.3
Cow	19	8	27	3.8
Pig	18.2	12.2	30.4	4
Sheep	8.2	4.2	12.4	4

Table 2 MCF of different sources.

Source	MCF (%)
Pasture/dry lot	1
Solid storage	1
Liquid storage	39
Slurry channels <1 month	0
Slurry channels >1 month	39
Anaerobic (co)digestion	0–100

Little is known about the microbiological basis of methanogenesis in fresh manure, but the methanogenic potential in fresh manure is low, probably because of inhibitory concentrations of NH_3 derived from urine. There are, however, slow growing methanogens capable of adapting to as much as 7 g total ammoniacal N/l (i.e., *Methanosarcina* spp.), which develop in manure and anaerobic digesters.^[4] CH_4 is oxidized mainly by aerobic bacteria. Both methanogens and CH_4 -oxidizing bacteria are present in solid manure. Duan et al.^[5] reported the potential CH_4 oxidation in a surface crust to be 50–100 times more sensitive to nitrite (NO_2^-) than to ammonium (NH_4^+) or nitrate (NO_3^-), and <1 mM NO_2^- significantly inhibited CH_4 oxidation activity. Besides storage temperature, moisture, and duration of storage, there are several other factors influencing slurry-derived CH_4 emissions, such as stirring, aeration, and slurry tank coverage. Another important factor is the use of an inoculum to reduce the start-up time of CH_4 production by providing already established microbe populations. Additionally, the dilution factor of slurry may also affect CH_4 emissions. Hindrichsen et al.^[6] observed that feeding treatments causing a higher enteric CH_4 formation resulted in lower CH_4 emissions from the corresponding slurry, probably because of the lack of fermentable matter, which has already been spent in the animal's digestive tract.

Table 3 CH_4 produced from manure management.

Animal	Manure management (kg CH_4 /head/yr)
Dairy cows	13
Beef	6

Nitrous Oxide

N_2O is produced, directly and indirectly, during the storage and treatment of manure before it is applied to land. Direct emissions occur from different systems such as pasture, range, and paddock, and indirect emissions occur from the soil due to other forms of N loss from the systems. Even indirect N_2O losses (i.e., derived from NO_3^- leaching and NH_3 volatilization) can at times be larger than direct N_2O losses. The emission of N_2O from manure during storage and treatment depends on the N and C contents of manure and on the duration of the storage and type of treatment. Whereas CH_4 production and oxidation processes are associated with anoxic and oxic conditions, respectively, and emissions of N_2O are stimulated under O_2 -limited conditions. Direct N_2O emissions occur through combined nitrification and denitrification of N contained in the manure. Nitrification does not occur under anaerobic conditions. It is a two-step oxidation of $\text{NH}_3\text{-N}$ to $\text{NO}_3\text{-N}$, primarily carried out by NH_3 -oxidizing bacteria (AOB) and nitrite-oxidizing bacteria (NOB). NH_3 -oxidizing archaea have also been observed in composting manure and soil, but are not responsive to N inputs, and hence, their role is uncertain. N_2O is produced either by AOB, as a side-product in the conversion of NH_3 , or by a subsequent conversion of NO_2^- through nitrifier-denitrification process. Denitrification is the transformation of nitrites and nitrates to N_2O and dinitrogen (N_2). The ratio of $\text{N}_2\text{O}/\text{N}_2$ increases with increasing acidity, nitrate concentration, and reducing moisture content. Denitrification is carried out by a phylogenetically diverse group of heterotrophic bacteria, although the process has also been observed among fungi and archaea. Most denitrifiers are facultative anaerobes, i.e., they prefer O_2 as electron acceptor but can use NO_3^- or NO_2^- in the absence of O_2 . The expression of genes for denitrifying enzymes is stimulated at low O_2 levels, but N_2O reductase is unstable even with traces of O_2 . Therefore, N_2O can accumulate around oxic–anoxic interfaces in the manure. Chemical gradients can also develop, which may influence N_2O emissions. Around air–liquid interfaces, CO_2 and NH_3 will be lost to the gas phase, thereby removing the buffering capacity and alkalinity. As NH_3 oxidation is an acidifying process, there is thus a potential for significant reduction in pH because of nitrification. Fukumoto^[7] showed that the addition of NOB to a compost prevented NO_2^- accumulation and N_2O emission. In summary, the production and emission of N_2O from managed manures require the presence of either nitrites or nitrates in an anaerobic environment preceded by aerobic conditions necessary for the formation of these oxidized forms of N. In addition, conditions preventing reduction from N_2O to N_2 (e.g., a low pH or limited moisture) must also be present. If pH declines, rates of nitrification and denitrification may also decline, but the $\text{N}_2\text{O}/\text{N}_2$ ratio of denitrification will increase. Table 4 describes the composition of manure in different livestock species.

Table 4 Composition of manure in different livestock species.

Livestock	Moisture content (% wet basis)	Total manure (L/day/animal)	Total solids content (kg/day/animal)	Total volatile solids (kg/day/animal)
Dairy cattle	87	68.14	9.07	7.71
Beef cattle	92	29.60	2.31	1.89
Poultry broiler	74	0.10	0.03	0.02
Pig	90	4.73	0.45	0.37

Nitric Oxide

NO is emitted from soils through nitrification in the surface layers of stored manure or in manure aerated to reduce odor or to promote composting. Increased nitrification is likely to occur following the application of manures and deposition of excreta during grazing.

Ammonia

Agricultural activities and concentrated animal feeding operations account for up to 80% of the total NH_3 emissions on a global scale.^[8] NH_3 can volatilize from solids and liquids separation area, manure storage facilities (under floor pits and anaerobic lagoons), and also land application of manure. The relationships between NH_3 volatilization and factors such as air velocity and turbulence, manure temperature, and pH have been well documented.^[9] The source of NH_3 emission from manure management is the N excreted by the livestock. The excretion of N, and the subsequent emissions of NH_3 , varies between livestock species (e.g., cattle and pigs). Within a livestock species, there are large differences between animals raised for different purposes (e.g., dairy cattle vs. beef cattle). In general, only the $\text{NH}_3\text{-N}$ is susceptible to loss by volatilization from dairy wastewater into the atmosphere.^[10] About 75–80% of the total N entering a dairy facility is lost from an anaerobic lagoon through gaseous emissions and only 20–25% of total N retained in the lagoon liquid being available for fertilizing croplands or pastures.^[11] NH_3 volatilization is generally the largest pathway of the loss of manure N, with losses typically accounting for 30–70% of the NH_4^+ content of cattle manure. In ruminants, the conversion of feed N into milk and meat is an inefficient process, and approximately 75–80% of the feed N intake is excreted in urine and feces.^[12] NH_3 can only be volatilized when urinary N (urea) is hydrolyzed by the enzyme urease present in the feces and not in the urine. NH_3 emissions from livestock manures during and after field application depend on properties of the manure, including viscosity, total $\text{NH}_3\text{-N}$, C contents, and pH.

Non- CH_4 Volatile Organic Compounds

The NMVOCs are defined as all those artificial organic compounds other than CH_4 , which can produce

photochemical oxidants by reaction with N oxides in the presence of sunlight. NMVOCs from animal production originate from feed, especially silage, and from partly digested and undigested fat, carbohydrates, and protein that decompose in manure. Consequently, anything that affects the rate of manure management (e.g., manure management in the stable and storage, straw added to the manure, duration of storage, and manure application) affects NMVOC emission. Sites of emission include livestock buildings, yards, manure stores, and fields on which the manure is spread. These emissions depend on the actual temperature and the wind speed over the surface. Up to 50% of the NMVOC from animal handling is isopropanol and n-propanol followed by acetaldehyde and short-chain acids such as acetic acid, propionic acid, and butanoic acid.^[13] Dimethyl sulfide comprises approximately 1–3% of the NMVOC emission. Ethyl acetate and dimethyl disulfide occur in larger concentrations in cattle and poultry barns, respectively. These compounds contribute strongly to the odor associated with manure.

GENERAL MANURE MANAGEMENT STRATEGIES

The following are the general strategies by which manure can be effectively managed:

1. Using animal genetics, phase feeding (altering feed to match the age, growth, and production level of animals), and amino acid supplements as management tools to reduce GHG emissions.
2. Selecting livestock to genetically improve the efficiency of feed conversion by the animal.
3. Feeding less frequently and increasing the feed digestibility by mechanical (chopping, grinding, or pelleting feed), chemical, or biological processing.
4. Feeding livestock based on age, sex, and stage of production to match diet according to the nutritional requirements.
5. Using additives and improved nutrient utilization in animals' diets to simplify manure management at all stages of handling and disposal by reducing the amount of nutrients in waste.^[14] The goal of feed management is to match the nutrient needs of animals more closely with nutrients in feed.

6. Trapping air vented from production houses and treating it before discharge to the atmosphere to reduce odorous compounds, NH_3 , and other gases. Treatment processes include ozonation and biofilters,^[15] which do not affect the N content of manure.
7. Spreading manure evenly around the pasture and maintaining healthy pastures by implementing beneficial management grazing practices, such as rotational grazing, to improve the quality of forages resulting in increased animal productivity and lower gas emissions.
8. Applying swine manure treatment strategies based on physical, chemical, and biological processes that are able to reduce manure's pollution potential and convert them into valuable by-products such as biomethane (i.e., heat and electricity), organic fertilizers, and C credits (certified emissions reductions).^[16]
9. Avoiding application of excess amounts of manure because nutrients can be lost to the environment. Testing both the soil and the manure before application ensures the proper nutrient balance for plant needs and can help reduce the loss of nutrients as gases.
10. Integrating animal and crop production systems by reusing manure in plant production.

EVALUATION OF MITIGATION STRATEGIES

The nature of the N cycle and its interaction with the C cycle demand a holistic approach for addressing gaseous emissions and mitigation research.

- Handling manure as a solid or depositing it on pasture rather than storing it in a liquid-based system such as a lagoon would likely reduce CH_4 emissions but may increase N_2O emissions.
- Developing of compact models of biogas plants efficiently by using dung and urine for production of biogas, while reducing emission of CH_4 and N_2O .
- Using manure application techniques such as subsurface injection to reduce NH_3 and CH_4 emissions but resulting in increased N_2O emissions. Injection works well when combined with anaerobic (co)digestion and solids separation by improving infiltration.^[17]
- Using practices that result in the reduction of CH_4 production but increase in N_2O emissions (e.g., aeration of manure during storage to reduce CH_4 emissions but increase in N_2O emissions when aeration rate is sufficient to create an aerobic environment because of the nature of the antagonistic processes resulting in CH_4 and N_2O emissions).
- Recognizing the complex relationship between manure NH_3 volatilization and N_2O emission, because emissions of both may be reduced by diet manipulation or manure management. If a mitigation technology reduces NH_3 losses, the preserved NH_4^+ may later

increase soil N_2O emissions.^[18] On the other hand, gaseous losses of N may reduce the availability of N for nitrification and denitrification processes and, consequently, N_2O formation.^[19]

- Including low protein levels and creating a proper balance of amino acids in the diet to minimize the amount of N excreted, particularly in urine, namely feeding pigs low-protein diets with synthetic amino acids to reduce N being excreted in urine, reducing NH_3 volatilization, and decreasing NO_2 emissions.
- Using soil/plant testing to determine fertilizer needs, limiting N mineralization by minimizing fallow periods, optimizing split application schemes, and matching N supply with crop demand reduce emissions of NH_3 , N_2O , and NO gases.

CONCLUSIONS

There are numerous interactions between the animal, storage, and land application phases of the manure management process, and management at one stage affects manure composition and gaseous emissions at subsequent stages. Therefore, mitigation practices should not be evaluated individually in isolation but as the entire continuum of manure management and treatment. The latter warrants the use of whole-farm models. System-based modeling must play a key role in integrating the complexity of management and environmental controls on GHG emissions. As production of these gases is of microbial origin, the dry matter content and temperature of manure and soil are key factors in farm manure management decisions that influence the magnitude of their emission. There are a number of manure management practices that are feasible and can effectively reduce GHG emissions from manure storage and/or land application.

FUTURE PERSPECTIVES

The main barrier to widespread implementation of manure GHG mitigation strategies is the lack of knowledge about the technology or conservatism within the sector. This warrants education of the farming community about the positive benefits of anaerobic (co)digestion, supported by incentives through grants or long-term, low-interest loans to reduce the initial costs of capital equipment. Assistance in setting up farming cooperatives with shared digester facilities would also aid the development of community level anaerobic (co)digestion schemes. It is crucial to evaluate and develop cost-effective methods that producers can choose to mitigate GHG emissions from concentrated animal feeding operations in order to comply with contemporary and future legislations. To set standards for all these gaseous pollutants, technologies are needed to estimate their respective concentrations in the air. Additional

research is needed about the impact of soil type on the emission factors and on the C sequestration in relation with use of mineral fertilizer and FYM.

Manure: Compost and Biosolids

Bahman Eghball

Kenneth A. Barbarick

Colorado State University, Fort Collins, Colorado, U.S.A.

Abstract

Manure, compost, and biosolids (municipal sludge) are organic residuals that contain nutrients and organic matter. They are excellent substitutes for chemical fertilizers. The organic matter in these renewable organic residuals can significantly improve the chemical and physical properties of soil and enhance biological activities. Because manure, compost, and biosolids contain nutrients and organic matter, they can be used to improve degraded, eroded, or less productive soils as soil amendments. If not used properly, manure, compost, and biosolids can be sources of environmental pollution.

MANURE

Manure (animal waste) is generated in beef cattle feedlots, swine operations, dairy barns, poultry houses, and other livestock operations. The number of animals and the number of large production facilities in United States have significantly increased in the past years.^[1] Manure, as well as composts and biosolids, is a renewable resource and an excellent source of macronutrients [nitrogen (N), phosphorus (P), potassium (K), calcium (Ca), magnesium (Mg), and sulphur (S)] and micronutrients [zinc (Zn), copper (Cu), iron (Fe), manganese (Mn), etc.] that are essential for growing plants. For centuries, manure was used throughout the world for improving soil fertility and enhancing crop productivity. However, with the advent of synthetic fertilizers after World War II, manure was considered more a liability than a nutrient resource for crop production.

When animals are grazing on pastures and rangelands, manure is dispersed across a large area and little management is needed because the material is not concentrated and decomposes rapidly. However, when animals are concentrated in small feeding areas, the quantity of manure requiring proper management increases greatly. Significant amounts of manure are generated each year in United States from the confined feedlots of major livestock species (Table 1). The amount of N, P, and K present in the manure from these species would replace 25%, 25%, and 45% of the purchased N, P, and K fertilizers, respectively, in United States, if utilized at agronomic application rates (Table 1). However, because of the high hauling cost, replacement of fertilizer is limited to specific areas in the country where the animal feeding operations are located.

Crop producers are also reluctant to use manure because of factors such as hauling and spreading costs, potential introduction of weed seeds, non-availability of manure where needed, uncertainty about availability of manure nutrients to plants, and problems of odor and application uniformity. The global numbers of major livestock species are given in Table 2.

Even though manure is an excellent source of multiple nutrients and organic matter, it can also contribute to water, air, and land pollution because of the potential for environmental loading with excess P, nitrate, salts, undesirable microorganisms, pathogens (disease-causing organisms), and greenhouse gases. Manure application in excess of crop needs can cause a significant build up of P, N, trace elements [arsenic (As), cadmium (Cd), lead (Pb), mercury (Hg), molybdenum (Mo), nickel (Ni), Cu, Fe, Mn, selenium (Se), and Zn], and salts in soils. Trace-element limits in soil are given in Table 3. The elevated P and N levels in soil are of environmental concern when these nutrients are carried by runoff to streams and lakes and cause “eutrophication,” which is the nutrient enrichment of water that can promote algal growth and depletion of dissolved oxygen in water. This oxygen is essential for aquatic animals. Pathogens (such as bacteria, viruses, and parasites) in runoff from fields treated with manure can be another source of water pollution. Pathogens and odorous materials can also be carried by wind from the feeding operations to neighboring areas. Excess manure application can contaminate the groundwater with nitrate–N. Nitrate is a water-soluble ion that moves with water into the soil and can reach the groundwater within few days after application. The U.S. Environmental Protection Agency (USEPA) has set a 10 mg NO₃–N/L standard for drinking water.

Table 1 Annual manure, N, P, and K generated by animals confined in beef cattle feedlots, dairy barns, poultry and swine operations, and fertilizer use in United States.

Animal species	Animals on feed ^a (million)	Manure (dry weight; million Mg)	N ^b (Mg × 1000)	P ^b (Mg × 1000)	K ^b (Mg × 1000)

COMPOST

Composting is the aerobic decomposition of organic materials in the thermophilic temperature range of 40–65°C. The composted material should be an odorless, fine textured, low-moisture content material that can be bagged and sold for use in gardens, potting, and nurseries or used as a source of nutrients and organic matter on cropland with little fly-breeding potential. Other advantages of composting include improving the handling characteristics of any organic residue by reducing its volume and weight. Composting also has the potential to kill pathogens and weed seeds. Disadvantages of composting organic residues include loss of N and other nutrients during composting, the time taken for processing, cost of handling equipment, need for available land for composting, odors during composting, marketing, diversion of manure or residue from cropland, and slow release of available nutrients. Similar to manure or biosolids, composts can cause water, air, and land pollution if not used properly.

Temperature, water content, C/N ratio, pH level, aeration rate, and the physical structure of organic materials are important factors influencing the rate and efficiency of the composting process. Ideal values for these factors include a temperature of 54–60°C, C/N ratio of 25:1–30:1, 50–60% moisture content, oxygen concentration >5%, pH of 6.5–8.0, and particle size of 3–13 mm. The requirement set

by the USEPA regulations for composting municipal waste is that the temperature should be maintained at 55°C or above for at least three days so as to destroy the pathogens. A temperature of 63°C within the compost pile is needed to destroy the weed seeds.

Homogeneous manure solids can be composted alone without mixing with bulk materials. Bulking agents are required to provide structural support when manure solids, or other organic residues, are too wet to maintain air space within the composting pile, to reduce water content, and/or to change the C/N ratio. Dry and fibrous materials, such as saw dust, leaves, and finely chopped straw or peat moss, are good bulking agents for composting wet manure or organic residues. Depending on the ambient temperature, a complete composting process may take 2 to 6 months.

There are a number of methods for composting organic materials. These include active windrow (with turning), passive composting piles, passively aerated windrow (supplying air through perforated pipes embedded in the windrow), active aerated windrow (forced air), bins, rectangular agitated beds, silos, rotating drums, containers, anaerobic digestion, and vermicompost (using earthworms). Carcass composting can be done by using all types of animals. Mortality composting can be accomplished in backyard-type bins, indicator composter bins, and temporary open bins using layers of saw dust or chopped straw and dead animals. Water content is an important factor to be considered when composting dead animals and should be maintained at about 40–50%.

BIOSOLIDS

Treatment of municipal wastewater results in a mostly organic by-product known as “biosolids.” Land application of biosolids for beneficial use has been practiced since the early 20th century in United States. The USEPA announced

Table 3 USEPA (40CFR503.13, revised July 1, 1999), trace element limits, and concentrations in Littleton/Englewood, CO biosolids, July 27, 1999.

Trace element	Agronomic rate concentration limit (mg/kg)	Ceiling concentration limit (mg/kg)	Annual soil loading limit (kg/ha)	Cumulative soil loading limit (kg/ha)	Littleton/Englewood biosolids (mg/kg)
As	41	75	2.0	41	2.7
Cd	39	85	1.9	39	5.6
Cu	1500	4300	75	1500	256
Pb	300	840	15	300	46
Hg	17	57	0.85	17	1.2
Mo	—	75	—	—	8.0
Ni	420	420	21	420	15
Se	100	100	5.0	100	4.6
Zn	2800	7500	140	2800	198

Note: Concentration and quantities are on dry weight basis.

requirements regarding beneficial use of biosolids with promulgation of the 40 CFR503 regulations in February 1993. The USEPA and the state agencies that control land application of biosolids encourage the judicious recycling of biosolids on crop- or rangeland, as they contain essential plant nutrients and organic matter.

A key aspect of USEPA and Colorado Department of Health (CDH) regulations requires the application of biosolids at an agronomic rate. The CDH^[5] defines agronomic rate as “the rate at which biosolids are applied to land such that the amount of N required by the food crop, feed crop, fiber crop, cover crop, or vegetation grown on the land is supplied over a defined growth period, and such that the amount of N in the biosolids which passes below the root zone of the crop or vegetation grown to groundwater is minimized.” The USEPA trace-element limits for land application of biosolids are shown in Table 3. State agencies that control biosolids recycling on land are required to adopt these limits as minimum requirements to protect the environment and public health. Risk assessment of different biological pathways served as the foundation for establishing the trace-element restrictions. For example, the concentrations for Littleton/Englewood biosolids shown in Table 3 indicate that it meets the agronomic-rate limits and can, therefore, be applied at an agronomic rate with minimal restriction. New, aggressive pretreatment programs have significantly reduced trace-element concentration in biosolids since about 1970, and therefore, environmental and public health risks are even more minimal.

The USEPA requires municipal wastewater treatment facilities to reduce pathogens and to reduce the attraction of insects and animals before applying biosolids to land. Most municipal wastewater treatment plants use heat and attack by beneficent microorganisms through anaerobic (without air) or aerobic (with air) digestion to kill potential pathogens and reduce odors that may reside in wastewater. Municipalities accomplish further reduction of pathogens and stabilization by composting, drying, or other techniques.

The major reason that the USEPA promotes land application of biosolids is that the plant nutrients and organic matter can benefit the soil–plant agroecosystem. For example, Littleton/Englewood biosolids used at two research locations contained up to 5.0% organic–N, 1.3% ammonium–N, 140 mg/kg nitrate–N, 3.7% P, and 0.30% K. Biosolids can also provide plant micronutrients such as Fe and Zn. The organic carbon in biosolids can help to develop and stabilize soil structure with a concomitant increase in precipitation capture and decrease in soil erosion. Efficacious land application of biosolids changes the perspective from disposal of a waste (i.e., a nuisance) to recycling a valuable resource (i.e., a beneficial process).

CONCLUSION

Organic residuals (wastes) can serve as excellent sources of plant nutrients such as N, P, and micronutrients, namely Fe and Zn. Proper management is required, however, to match nutrient amounts supplied by the organic materials with crop needs so as to avoid potential pollution problems.

Mapping Soil Carbon

Budiman Minasny

Brendan Malone

Alex B. McBratney

Department of Environmental Sciences, University of Sydney, Sydney, New South Wales, Australia

Abstract

The soil system is recognized as a significant terrestrial sink of carbon. Mapping and predicting the spatial distribution of soil carbon have been of great interest, as demonstrated by the increasing number of publications in mapping soil carbon stock globally and nationally. This entry gives an overview of mapping soil carbon based on traditional soil maps to modern digital mapping technologies.

The soil system is recognized as a significant terrestrial sink of carbon. Mapping and predicting the spatial distribution of soil carbon have been of great interest, as demonstrated by the increasing number of publications in mapping soil carbon stock globally and nationally.^[1,2] However, it is also a challenge as evidenced by the large variation of soil carbon concentration observed at field, continental, and global scales (Fig. 1). Soil carbon mapping and the knowledge of the spatial distribution of soil carbon are useful to: 1) provide a baseline carbon level; 2) assist in soil management for agricultural production and ecosystem services; 3) identify critical areas for monitoring soil conditions; 4) identify potential areas for soil-based carbon sequestration; and 5) serve as an input into process-based simulation models.

There is a fundamental difference between mapping soil carbon and carbon auditing. For carbon auditing, we are only interested in the total amount of carbon in the soil within a given spatial domain. Therefore, it is not necessary to be mapped.^[3] The product of digital mapping, however, is maps of the spatial distribution of soil carbon, and while we can use mapping for temporal soil carbon auditing, it will generally be an expensive exercise.

Traditionally, soil carbon estimates are based on soil maps using soil–landscape and vegetation associations.^[4] At the continental scale, the resulting maps are usually at the cartographic scale of 1:1,000,000 or coarser, e.g., Africa^[5] and Brazil.^[6] These maps are useful where there is little soil information for the area of interest. There are several versions of global soil carbon maps, and these are mainly derived from the Food and Agriculture Organization soil map and the Harmonized World Soil Database, such as^[7] at a resolution of 30 arc seconds or the United Nations Environment Programme's World Conservation Monitoring Centre updated Global Carbon Map.^[8] Global estimations of soil carbon stocks from the global maps range between 1200 and 2470 for the upper 1-m profile^[4,7]

that were derived from different data and regression models. In any case, these estimates of soil carbon stocks have no quantified uncertainty associated with them.

Traditional soil mapping has been difficult and time-consuming due to the great soil spatial variation. In addition, much soil information is lost because they are mapped in polygons reflecting soil types or classes and there is no quantified uncertainty associated with them. The development of digital soil mapping technologies arose in the 1990s^[9] and formalized by McBratney, Mendonça Santos, and Minasny^[10] These technologies align with the progress in digital earth observation with massive spatial data generated by remote and on-the-ground sensors. Concurrently, mathematical and statistical techniques have been developed that allow for the prediction of soil properties in areas with little information as well as indicating the uncertainty of the predictions. The digital revolution has transformed many of the sciences, e.g., soil carbon concentration is mapped as a continuous function of depth, as soil carbon stock can be readily calculated at any depth.^[11] These maps are stored and manipulated in digital form within a geographic information system environment, creating the possibility of vast arrays of data for analysis and interpretation. A review of digital mapping of soil carbon is presented in the study by Minasny et al.^[2]

The basis of digital soil mapping is that the soil property (carbon content) is related to its environmental factors and can be expressed as a spatial soil prediction function. This is called the “*scorpan*” spatial prediction function:

$$C_{x,z} = f(s, c, o, r, p, a, n) + e$$

where soil carbon concentration C (either as a mass fraction kg C per kg soil or as a density kg C per m³ volume of soil) at spatial position x and depth z is a function of soil factors (s), climate (c), organisms that include land use, human effects, and management (o), relief (r),

Fig. 1 A global map of soil organic carbon content at the depth of 0–10 cm. The map was generated using an empirical model relating the soil carbon data from the International Soil Reference and Information Centre–World Inventory of Soil Emission global profile database to climate (mean annual temperature, precipitation, radiation, and evapotranspiration) and a topographic variables (topographic wetness index). The graph on the right represents the variation of soil organic carbon with latitude.

parent materials (p), age or time (a), spatial position (n), and the spatially correlated errors (e). Soil variables such as an existing soil map “s” can also be used as a predictor. The form of *f* can be simple linear models^[12] to more sophisticated data mining tools.^[13] Soil observations are fitted to model the relationship between the soil carbon concentration and their *scorpan* factors. This is followed by using the fitted model to predict at all locations of the mapping extent. This approach is quantitative and relies on the assumption that the soil observations cover the whole-range variation in environments, so that the model can be extrapolated to the whole area.

The soil carbon maps, produced using digital soil mapping techniques, have been applied at various grid spacing and extents, from global,^[12] continental,^[14,15] national,^[13,16,17] regional, catchment,^[18–20] farm or field,^[21,22] and urban areas.^[23]

Soil organic carbon is most often mapped; however, inorganic carbon has also been mapped,^[24] as has different pools of carbon^[19] and soil carbon saturation index.^[25] Another important challenge is in mapping areas with peat soils, where the environmental (*scorpan*) relationships between soil organic carbon in peat and mineral soils can be quite different.^[26]

Global soil initiatives such as GlobalSoilMap have been developed by a consortium that aims to create a digital map of the world’s soil properties, including soil carbon.^[27] This global effort will provide access to the best available map of soil properties across the globe at a resolution of 100 m along with its 90% confidence of prediction, in a consistent format at the depth ranges of 0–5, 5–15, 15–30, 30–60, 60–100, and 100–200 cm. Realizing that it is a significant effort to apply the *scorpan* prediction function across the globe, the approach taken for global soil mapping is a pragmatic one. The methods that are used (or will be used) for mapping consider the nature, availability, and density of the existing soil data. A first approach of mapping soil carbon in the United States is based on a 1:250,000 soil map from the U.S. Department of

Agriculture–Natural Resources Conservation Service, where the soil polygons were converted to raster estimates of organic carbon content for the 6 depth intervals of the GlobalSoilMap specification.^[28] This effort is mirrored elsewhere around the globe.

In addition to mapping the baseline soil carbon, digital maps can be used to map or estimate soil carbon change with time. When soil carbon data over space and time are available, they can be interpolated using spatiotemporal kriging. However, this approach is not dynamic and cannot be extrapolated for scenario modelling. On the other hand, the digital map of soil carbon is usually used in a mechanistic model to predict the change of C under different scenarios. The challenge in mapping soil carbon in space and time is to use a more mechanistic and dynamic relationships analyzing the spatial and temporal carbon data.^[29]

Abstract

The soil organic carbon (SOC) stocks of each geographical region based on the World Reference Base (WRB) soil classes of the country were determined seeking their contemporary and/or future use for national crop/soil use policies and for the credible assessment to mitigate atmospheric carbon dioxide and restore degraded soils. Once the SOC stocks are mapped, it is important to take the necessary measures for improving land management for increasing SOC stock and enhancing quality of agricultural soils. Total SOC stock of soil in Turkey is 9.23 Pg up to 0.7 m depth, and annual emission from the agricultural sector is 25.7 Tg C.

INTRODUCTION

The total carbon dioxide (CO₂) emissions of 25.7 Tg (Tg = teragram = 10¹² g = 1 million metric ton) from the agricultural sector (Turkish Statistical Institute, 2011) were only about 7% of the total national emissions (369.7 Tg) for

Turkey in 2009.^[1] The carbon-sink capacity of the two land-based reservoirs in Turkey, namely the soils and vegetation, is affected by anthropogenic activities such as soil sealing and land use change. Drastic changes in land use and the resultant degradation of soil quality have depleted the carbon (C) reserves in the country, i.e., a reduction in soil

organic matter (SOM) content of the managed soils and, in turn, of the forest ecosystems. Nevertheless, there exists a vast potential to sequester C through conservation and restoration of soil quality and improvement in the vegetation cover of the different Terroirs and/or Anthroscapes or human-resaped historical landscapes^[2,3] of Turkey by “sustainable land management.” Thus, the objective of this study was to prepare the soil organic carbon (SOC) stock map and assess the C-sequestration potential of the Turkish soils.

MATERIALS AND METHODS

The first step in mapping the SOC stocks of the soils of Turkey was accomplished by the partial renovation of the previous soil maps prepared by the General Directorate (GD) of Agricultural Reform (the previous GD of Rural Affairs and GD of Soil and Water) of the Ministry of Food, Agriculture, and Livestock of Turkey via site-specific field work and profile descriptions based upon expert knowledge. Additionally, recently accomplished 5368 SOM analyses, of the 0–20 cm layer, by the modified Walkley Black Method,^[4] for soils of different slightly-modified Köppen–Geiger climatic regions (Central, Western, Eastern, South Eastern, and Northern Anatolia regions and the region of the Mediterranean–Aegean–Northern Marmara)^[5,6] were compiled for C-stock calculations. Moreover, land use and plant cover characteristics were integrated in the SOM database. The SOM analyses were provided from the laboratories of the Universities of Adnan Menderes, Çukurova, Ege, Harran, Selçuk and 19 Mayıs and the Institutes of Central Research

of Soil, Fertilisers and Water and Soil, Water in Ankara and Agricultural Meteorology Research of Atatürk in Kırklareli.

The SOM values of the World Reference Base (WRB) soil classes were extended countrywide for each of the six geographical soil regions by means of geographic information system, i.e., the SOM values of each WRB soil groups of a specific region were extended/assigned (pedo-transferred via local expert knowledge) to similar soils of that geographical region. Ultimately, the Carbon Stocks Map of the Soils of Turkey was accomplished via the formula given according to the WRB (2014) soil map for each soil group at 0–20 cm depth.

$$\text{SOC stock (Mg ha}^{-1}\text{)} = \sum_i^n \text{soil volume (m}^3 \text{ ha}^{-1}\text{)} \\ \times \text{soil bulk density (Mg m}^{-3}\text{)} \\ \times \text{SOC concentration (Mg Mg}^{-1}\text{)} \\ \times \text{area (ha)}$$

where n is the number of the soil layers (0–20 cm soil depth only). The bulk density was calculated by the Saxton texture triangle.^[7] Data reported as SOM concentration were converted to SOC by multiplying with a conversion factor of 0.58.^[8]

RESULTS AND DISCUSSION

An enhanced diversity in the type of soils of the country was determined based on the highly variable and undulating topography, parent materials, vegetation, and

Fig. 1 The soil map of Turkey according to the IUSS Working Group on WRB (2014).

the effects of the present and/or past climates on soil development with evidence of prevalence at numerous locations (Fig. 1).

In general, higher SOC stocks occur in the Mediterranean, Aegean, and Northern Marmara and Northern Anatolia, Central Anatolia, and the lowest in Southeastern Anatolia (Fig. 2). The SOC stocks follow a *decreasing* order from West Anatolia to the East and Southeast. The higher SOC stock of the Mediterranean region (706.22 Tg) than that of the Black Sea region (501.85 Tg), despite higher precipitation (~2500 mm annual rainfall) and dense vegetation cover (coniferous forests and cultivated *Corylus avellana*, *Camellia sinensis*, and *Zea mays*; Table 1 and Fig. 2) of the latter, are due to its larger land area. On the other hand, the Tauride Mountain forests of the Mediterranean region, such as the maquis (the Mediterranean scrub), the traditional olives, and carobs of the Tauride slopes are the major land cover which increase the SOC stock of the Mediterranean and Aegean regions. Koçak and Kapur^[9] and Rezzaghi et al.^[10] have determined high amounts of SOM in the red pine–oak community (11%), maquis (10%), *Olea europaea* (≥7%), and *Ceratonia siliqua* (≥8%in the) root-zone soils of the eastern Mediterranean

Table 1 Areas and SOC stocks according to the regions.

Regions	Area (ha)	SOC stock (Tg)
Central Anatolia	9,467,349.77	249.33
Mediterranean, Aegean, and North of the Marmara Regions	23,806,283.69	706.22
Northern Anatolia	10,893,328.70	501.85
Western Aegean	13,499,603.54	332.26
Eastern Anatolia	14,551,530.26	278.23
Southeastern Anatolia	7,541,446.08	158.97
Total	79,759,542.05	2,226.85
		2.23 (Pg)

part of Turkey, i.e., the eastern Tauride slopes. The widely spread Calcisols and Cambisols of Central Anatolia (Fig. 1) and the Cambisols and Leptosols of eastern Anatolia have been used extensively as small grazing rangelands since the Roman and Ottoman periods and for the cultivation of rainfed wheat. These soils along with the inland Arenosols (Fig. 1) of the Konya-Karapınar area are the potentially high C sequestering soils of the country, if appropriately

Fig. 2 SOC stocks of Turkey.

managed.^[11] This area is one of the bread baskets of Turkey together with eastern Anatolia area used for cultivation of wheat irrigated with ground water and surface sources collected in reservoirs. The coastal Arenosols and that include the wetlands are also the potentially high C sequestering areas of the country. Yaktı et al.^[12] stated that the SOC contents of leveled Arenosols were increased several folds in 20 years thanks to governmental forest management projects under cypress and eucalypts canopies. Despite the contradictory views repeatedly stated by nature conservation scientists, Polat and Kapur^[13] revealed an eightfold increase within 40–50 years in the country indicating the high potential of Arenosols in sequestering C in the soil, under appropriate forest management.

CONCLUSION

The SOC stocks of Turkey for the top 20 cm (2.23 Pg C) are comparable to that of France's 3.26 ± 0.872 Pg C,^[14] a country almost as large as Turkey.^[15]

It is widely recognized that with judicious cultivation and management, despite the large vegetative diversity and high agricultural potential, Turkey is faced with a dilemma of soil degradation by salinization and desertification. Thus, recarbonization of soils of Turkey is critical to the mitigation of greenhouse gas emissions and restoration of soil fertility. Further, the SOC stock must be credibly assessed to mitigate atmospheric CO₂ and restore degraded soils. Once the SOC stocks are mapped, it is important to take the necessary measures for improving land management for increasing SOC stock and enhancing quality of agricultural soils.

Abstract

Soil has long been used for manufacturing diverse materials alongside its major function as the medium of plant growth offering all the knowledge attained over millennia via its consumers. Its major use as an ingredient of pottery and construction materials is a process that causes the irreversible overuse of this highly precious natural material. However, contemporary land use approaches such as the Anthroscape—a renovated land use approach based on the traditional knowledge attained by long-standing experience—promise a sustainable and appropriate use of soil.

INTRODUCTION

A Historical Perspective of Appropriate Use of Soil/Land

The soil, alongside its numerous uses, has been misused for the purpose of making pottery and constructing buildings since millennia by many civilizations, particularly, in the Mediterranean Basin, the cradle of the ancient societies. Fortunately, the initial and local efforts to limit such misuse were followed by the establishment of law and order during the Roman Empire. Terraces were built along the coastal slopes embellishing the bountiful nature that was and still is generous to all its inhabitants by conserving the soil and its water content. Such measures ultimately lead to the establishment of agroecosystems with dominant crop/tree systems such as the olive orchards of the Emperor Sebastian (Elaiussa Sebaste) as well as in Kızkalesi (Korykos) in Erdemli, Mersin, Turkey.^[1]

The terraces were the products of a unique long-developed concept through the integrated thinking that had advanced since the teachings of Aristotle of the School of Athens on the protection and management of nature. The Aristotelian holistic/organismic context developed for nature was based on the strong relationship and harmony between biotic and abiotic components (i.e., the living animals and plants and the non-living things such as rocks and soils). [Due to a demand for the implementation of integrated sustainable land and water management programs, which are in vain sought the Aristotelian holistic/organismic context developed for nature was based on the strong

relationship and harmony of the inanimate and animated components, i.e., the living (e.g., animals and plants) and the non-living things (e.g., the rocks and soils).]

The promising approach of the “Anthroscape” is based on reshaped long-standing human landscape that seeks a continuum in the Anthropocene. The concept was proposed by Crutzen,^[2] it delineates land degradation since the last 300 years^[3] and attempts to reconstruct a socioeconomic and physical methodology with regional indigenous specificities for the people. It is most likely the contemporary version of the Aristotelian concepts about nature and its management. This approach recommends the determination of sample sites of variable scales with particular and unique traditional knowledge throughout the developed and developing world and the development of sustainable land and water management programs. Finally, the concept also allocates land for industry, agriculture, and forestry, while it permits the extraction of raw materials for civil engineering structures.

Soil as a Building Material

Laterite

Laterite, formed by pedogenic processes, is a traditional building material. It has been used extensively as bricks in constructing local houses in India, throughout the Indian subcontinent, other parts of Asia, and South America. The sturdy buildings constructed from laterite have been proven to be resistant to the highly degrading effects of nature during the monsoon period as well as during the hot and

wet/dry summer months. Laterite houses are also preferred for their durability against earthquakes. These houses were also highly popular during the historical periods in Cambodia, which used laterite for the construction of the famous Angkor monuments^[4] and which endured the extreme environment for millennia. Laterite, a naturally occurring soil to civil engineers and an ultimate weathering product to pedologists, is a soil/material rich in goethite, hematite, kaolinite, and quartz. It is being extensively introduced for use as an additive in durable and cheap concrete in the tropics and subtropics. The material is also used as a “filler” for foundations, as a base material for highway construction, and for economic building “Blocks.”^[5]

Making cement

Soil materials are used in the manufacturing of cement and ultimately concrete, which are referred to as soil cement/roller-compacted concrete (RCC). The RCC has a zero-slump consistency. It is placed and compacted with earth-moving or paving equipment as soil cement. Soil cement is also known as the cement-modified soil and cement-treated aggregate base with materials denoted as pumice (scoria, expanded perlite, tufa, zeolite, etc.).

Soil cement is a dense, highly compacted mixture of soil or roadway material with Portland cement and water. Soil material can consist of any combination of sand, silt, clay, gravel, or crushed stone. Granular soils are preferred, however, because they pulverize more easily and require less cement to achieve the required strength and durability.^[6] Cement–soil mortars have been found to have a high tensile bond strength for use in soil–cement block couplets when compared to cement mortar and cement lime mortar.^[7]

As the soil cement is placed and compacted, the cement hydrates and the mix becomes a structural slab-like material. After construction and curing, soil cement is hardly affected by water or the freeze–thaw cycle. Therefore, it does not slump under construction traffic or rut during spring thaws, and it can also bridge over soft subgrade. This is the primary requirement for attaining high-quality and long-lived concrete, whereby the process of hydration has reached a state of maturity with the optimal formation and distribution of end-product minerals such as ettringite and portlandite^[8] (Fig. 1). The perfection of the hydration process is most likely due to the optimal ionic character of the soils and their pH. These properties influence the speed and uniformity of the ongoing reactions which make the unique Anatolian mortar—the Horasan mortar, and that was extensively used by the Romans, by Byzantines, and later by the Seljuks.

The contents of crushed/ground brick and lime, long slaked and softly burnt,^[9] together with the illite or smectite containing dominantly kaolinitic soil impart a unique character to the hydraulic/hydration properties of the Horasan mortar. In addition to its economic merits, Roman initial Horasan mortars with tufa fragments containing clay/soil

Fig. 1 Scanning electron microscopy (SEM) image of aggregates of clewing ettringites developing during hydration.

Source: Photo courtesy of Dr. Hanifi Binici, K.S. University, Kahramanmaraş, Turkey.

materials were also probably leached. Clay coatings onto the sedimentary tufa may have affected the binding strength as well as the consistency in the speed of the long slaking and slow burning of the Roman mortars recovered from several Spanish sites.^[10]

Soil in Earthfill Dams

Soils, other than the prime quality suitable for cultivation and agro-ecosystem management, are the most important components affecting the construction of earthfill embankments by their distribution, method of placement, water content, and compaction. Soils are mainly classified by their engineering properties into two main divisions using their textural characteristics, as soils of either coarse grains or fine grains. Coarse grains are those >200 sieve mesh size and include rocks, gravels, and sands. Fine grains are <200 sieve mesh size and include silts and clays. Coarse-grain material is used for the outer zones of an earthfill embankment, and fine-grain material is used for the impervious core or central portion of the dam.

The soil material must be placed in horizontal layers no more than 15 cm thick after being compacted and should be homogeneous and free from lenses, pockets, organic material, or other imperfections. Prior to placement, the material should have the optimum moisture content required for compaction. The optimum moisture content, or the water content that produces the maximum density, may be obtained by the Proctor test. Good compaction of a cohesive soil reduces permeability and increases the shear strength and the stability of the dam. Clay mineral contents of the fine core materials are primarily significant as the clay/soil core settles even after the construction of the dam and/or the completion of the field compaction process. Soil/clay cores extracted from soil types rich in smectite

(especially nontronite) tend to expand on wetting and create potentially disruptive forces in rockfill sections. These soils settle differentially and lead to erosion of the core, thus jeopardizing the overall safety of the dam.^[11–13]

SOIL IN CERAMICS

Ancient Pottery

Ancient India of the Indus Valley civilizations (Harappa, Mohenjo Daro, and Lothal) had marvellous craftsmen skilled in pottery. The necessary raw material sources/alluvial soils (for making high-quality products like terracotta figurines) were bountiful throughout the Indus Basin. These materials were replenished year-round by the sequential deposition of soil via flooding by the waters collected from the Hindu Kush ranges.^[14,15] Much earlier, the Neolithic Çatalhöyük from Anatolia (the modern Turkey of today) was the cradle of civilization. People from this region were sustainably using soils and sediments for making mud bricks and pottery. These observations were based on the clues from the utilization of plant remains as well as the existence of suitable soil/clay sources in the vicinity (Fig. 2).^[16] The Hittites, who lived in present-day Turkey, were the masters of firing technologies in constructing updraft furnaces and of using the most appropriate soil/clay sources to successfully attain high and somewhat consistent temperatures as is indicated by the high vitrification observed in high-resolution electron images (Fig. 3).^[17] The Urartus, the early settlers of eastern Turkey (800–600 B.C.), were the expert craftsman of ceramics and were highly proficient in the firing technologies and production of vitrified slipware by the use of appropriate volcanic soil materials.^[18] The late Seljuks and Ottomans of İznik (the Byzantine Nycheia withholding the primary

Fig. 2 Broken reed remnants in a Neolithic shard from Çatalhöyük, Central Anatolia (SEM image).

clues of Anatolian pottery) discovered the superiority of buried furnaces with uniform and gradual low-rate increase of temperature along with the use of earth/soil materials rich in kaolinite and quartz as well as calcite, acting as a flux in heat control. These highly appropriate soil materials were located on the ancient terraces/shores of the Lake İznik and on the volcanic highlands of central and southern Turkey, which leads to the development of an ultimately superb microstructure (with high-temperature minerals) of high durability and artistic properties (Figs. 4 and 5).

The renowned Deruta ceramics from Umbria, Italy, belonging to the Renaissance period, were manufactured from soils referred to as the clay raw materials. This was also the case in the production of indigenous ceramics throughout the historical periods. The material used was rich in calcite and was the driving force in the kinetics of firing together with the low heating rate.^[19] The process was similar to the earlier but highly advanced technology of the İznik ceramics of Turkey.^[20]

Advanced Ceramics

Besides the “traditional ceramics,” there is a new class of ceramics, called “advanced ceramics.” It emerged in the 20th century as the material systems became more refined, and special compounds and processes were developed for structural and electronic applications. These advanced ceramics

Fig. 4 Uniform glaze and coating in Iznik Ceramic (13th century).

Source: Data from the archive of the Department of Archeometry, University of Çukurova, Adana, Turkey.

are distinguished by their high chemical purity, careful processing, and high values of the useful properties.^[21]

Despite the development of the advanced high-technology ceramics, traditional ceramic production is used at a high rate due to the renovation of the furnace technologies and the increasing knowledge on the selection of the raw materials. Among the numerous contemporary examples for this are the studies undertaken by Kapur et al.^[17,22] and Kelling et al.^[23] These studies specifically

Fig. 5 Fibrous high-temperature minerals developing in glaze pore of a Seljuk ceramic (12th century).

Source: Data from the archive of the Department of Archeometry, University of Çukurova, Adana, Turkey.

involve the use of novel raw materials—rocks—such as basalts along with soils formed in/on basaltic rocks with conventional furnace technologies. These technologies have been renovated for economic and sustainable production, as well as for generating products that are more resistant to physical and chemical stresses.^[24]

ACKNOWLEDGMENTS

The authors are deeply indebted to Profs. E.A. FitzPatrick (University of Aberdeen, U.K.), Gilbert Kelling (University of Keele, U.K.), and Halet Çambel (Karatepe Open Air Museum, Turkey) for their invaluable contributions to the more than two decade-long studies conducted on the ancient ceramic materials in the Department of Archeometry, University of Çukurova. The principal author is also highly indebted to the valuable review undertaken by the editor.

Mediterranean Agriculture: Rainfed, Nitrogen Use Efficiency

Àngela D. Bosch Serra

Department of Environmental and Soil Sciences, University of Lleida, Lleida, Spain

Abstract

Mediterranean regions are the ones with a typical rainfall pattern, characterized by rainfall in winter and dry, hot summers. Strong water deficits occur for several months. Thus, nitrogen use efficiency (NUE) and its increase are linked to improvements in water availability and water use efficiency. NUE is lower in Mediterranean regions than in temperate areas, and large opportunities exist to improve it. Rainfed cereal crops are major nitrogen (N) consumers in these areas, and increases in NUE may be achieved through the proper design of the agricultural system. Proper timing of fertilizer operations, appropriate choice of N fertilizer type, and implementation of analytical tools adapted to the specific conditions are key issues, in addition to others, like conservation tillage or crop breeding. Some attention is paid to organic fertilization and more intensive rotations, avoiding bare fallow as a way to increase soil quality and overall NUE. To face these challenges, as the management complexity of the agricultural system increases, there is a strong need for developing channels for communication with land managers.

INTRODUCTION

Nitrogen use efficiency (NUE), a generic term in agronomic literature,^[1] is used here to indicate an overall nitrogen (N) efficiency; when possible, more specific terms are used.

Rainfed Mediterranean agriculture mainly encompasses cereals, such as barley and wheat (soft and durum), and tree crops such as almonds, olive trees, and vineyards.

Cereals are the greatest N fertilizer consumers in Mediterranean regions, a pattern that some authors^[1,2] signal to be worldwide, since cereals account for about 60% of N fertilizer.

The following discussion will mostly deal with agricultural practices and how improvements in N and agricultural system management may increase NUE. The discussion is restricted to areas that can support regular cultivation.

MEDITERRANEAN REGIONS

Mediterranean regions, associated with Mediterranean climate,^[3] are present in all continents.

The largest area lies between the temperate region (42° N) and the subtropical desert region (32° N), from the Eastern Atlantic coast to the Near East. Elsewhere, such denomination is given to South-Western Africa, western parts of America (California, Chile), and Southern Australia.

Winter rainfall is much larger than summer rainfall, and total rainfall amount per year ranges from 200 mm to over 900 mm. Some recharge of the soil profile takes place during the moist period, and some leaching might occur.

Water deficit may reach 8 months but always in the hottest period, with long days, and its intensity goes from arid to humid Mediterranean. Agronomic yields are affected by this erratic and irregular pattern of rainfall.

In Mediterranean regions, carbonate redistribution and clay illuviation are two of the main soil-forming processes.^[4] Soils are calcareous in the topsoil, salinity is present in some soils, soil water-holding capacity is highly variable, and soils have a low organic matter content. The pattern of net N mineralization in the major Mediterranean soils is similar, although the amounts of N mineralized may largely differ.^[5]

Since water is the most limiting factor in rainfed Mediterranean regions, its availability determines the characteristics of the agricultural systems.

The region around the Mediterranean may be divided into four main areas: arid areas with annual rainfall <250 mm (barley yields around 1500 kg/ha); semiarid areas with annual rainfall between 250 and 450 mm (average barley yields around 3500–4000 kg/ha); subhumid areas with annual rainfall between 400 and 700 mm, where soft wheat rather than barley is the main crop and, sometimes, legumes such as lentils, oilseed crops such as sunflower, or summer fiber crops such as cotton are included in the rotation; finally humid areas with an annual rainfall >700 mm, where summer crops such as alfalfa are easily introduced.

In California's dryland regions,^[6] annual rainfall ranges from 120 to 450 mm, and a crop–fallow system may be practiced in areas with rainfall <300 mm. Annual cropping with small grains (wheat and barley) is practiced where moisture conditions are more favorable.

In Southern Australia, where a Mediterranean climate prevails, ley farming (self-regenerating legumes such as *Trifolium* and *Medicago* cropped with wheat) practiced after 1945^[7] was very successful, but changes in the relative prices of wool and wheat have introduced a more intensive cropping, which relies on commercial fertilizers.

NITROGEN USE EFFICIENCY

There are many definitions of N efficiency parameters,^[8] but this discussion uses three of them, namely: nitrogen agronomic efficiency (NAE, kg/kg), defined as the ratio of (yield at N_x to yield at N_0) to applied N at N_x , N_0 means no N is applied; apparent nitrogen recovery (NRF, kg/kg), defined as the ratio of (N uptake at N_x to N uptake at N_0) to applied N at N_x ; and nitrogen physiological efficiency (NPE, kg/kg) is the ratio of (yield at N_x to yield at N_0) to (N uptake at N_x to N uptake at N_0). Thus, NAE (yield efficiency) is the product of NRF (N recovered) and NPE (yield and N recovered) and therefore reflects the overall efficiency with which applied N is used. NPE is directly analogous to NAE, where N recovered is substituted for N rate.

This analysis can be used to assess management impacts on the components of N efficiency,^[8] N utilization, and N retention in the cropping system.

The efficiency of N fertilizers applied to cereals across different climates, including the Mediterranean one, has been reviewed.^[9] Factors such as soils, fertilizer rate, source and management, and crop husbandry seem to have contributed as much to this variability as climatic factors. Such variability is also observed (Table 1) in semiarid Mediterranean regions in Spain where NAE ranges from 0 to 16 kg/kg, and NRF ranges from 0.12 to 0.9 kg/kg. Similar data have been reported in Greece.^[10]

Globally,^[1] average NAE for wheat is 18 kg grain/kg fertilizer. Apparent fertilizer recovery through the grain

cereal is estimated globally at 33%^[2] and is 42% and 29% in the developed and developing nations and about 50% for the aboveground biomass.^[1] Studies with ¹⁵N including the soil compartment have indicated higher figures^[11] of 66% for the first year.

Most of the available data are from research experiments. Thus, on-farm NUE may be less than these figures. Some authors guess,^[1] with available information, that actual farmer NRF values for aboveground wheat are between 20% and 30%, and under improved N management, NRF practices may reach 40%.

The low NRF under on-farm conditions indicates numerous opportunities to improve N use efficiency through management practices. Furthermore, NRF declines with increased rate of fertilizer use, which is usually low in many cases in the Mediterranean regions.

Increasing NUE in Mediterranean regions is based on a strategy of maximizing water use efficiency (WUE, aboveground biomass or grain dry weight per millimeter of water use) and increasing water use (transpiration plus evaporation from the soil) by the crop. These in turn call for a wide array of measures as rotations or conservation tillage.

Losses of the soil–crop system, which decrease sharply the N recovery efficiency, have been studied at different scale levels and environments: ammonium (NH_4^+) plant release,^[12] nitrate leaching, denitrification, ammonia (NH_3) volatilization. Losses due to volatilization, denitrification, and nitrate leaching altogether account for 20–50% of fertilizer N^[2] in studies using ¹⁵N. Under Mediterranean conditions, nitrate leaching is highly variable^[13] and denitrification may be low because of relatively good soil aeration. However, NH_3 volatilization may be high,^[14] because most of the soils are calcareous, with high pH in the topsoil.

Excess of available N in cereals grown in Mediterranean regions often leads to a situation of excessive vegetative growth and delayed maturity, which in turn results in low grain yields, a widely recognized process.

Table 1 Maximum grain yield (MGY), NAE, NRF, and NPE in different climatic Mediterranean regions in Spain.

Crop	MGY (10^{-3} kg/ha)	NAE (kg/kg)	NRF (%)	NPE (kg/kg)	References	Remarks
W	4.8	4.0–11.4	12–34	12–33	[15]

^aTotal crop nitrogen includes N in the root system. It accounts for 10–23% of total N; B: winter barley; W: winter wheat.

STRATEGIES TO IMPROVE N EFFICIENCY

Monitoring N in Soils and Crops

Large quantities of fertilizer N accumulate as nitrate in the soil profile in Mediterranean regions, particularly when high rates of N (mostly manure) are applied.^[18] Monitoring mineral N (N_{min}) in soils has two principal advantages: first, it allows to adjust N at sowing, according to the amount of residual soil mineral N, at tillering, or at the beginning of stem elongation in cereals, and second, it helps to control vegetative growth according to stored water at the end of winter period. Also, it prevents soil salinity to build up when an excessive amount of organic fertilizers is applied.^[19]

Available quick analysis methods in order to quantify N_{min} , at the time of fertilizer application, facilitate controls. This methodology can be complemented with other tools for N plant status diagnostic, such as optical measurements.

Nevertheless, usefulness of tools for N fertilization recommendations has to be locally tested and adapted; experience shows that they work very poorly when strong water deficit exists and fine tuning is needed.

N Fertilization: Type of Fertilizers and Timing

In the arid and semiarid Mediterranean climate of Ebro river valley in Spain, barley grain can increase 9–9.5 kg/ha/mm water conserved,^[5] raising yields by >300 kg/ha. In order to take the advantage of stored water at critical stages of flowering and grain filling, the amount of N applied and timing, in order to control unnecessary vegetative growth, is a key factor. Thus, applying N close to the time of maximum N demand of plants will increase N use efficiency. Usually, the greatest response to N fertilization occurs when the final increment of N is applied just to stem elongation in cereals.^[20]

A substantial proportion of applied N can be lost not only by leaching but also to the atmosphere as NH_3 gas,^[21] and NH_3 does not volatilize from dry soils. Nevertheless, when urea or NH_4^+ salts, or even pig slurry rich in NH_4^+-N ,^[14] are applied on the surface of calcareous soils, and a shower occurs, NH_3 losses can be important. Therefore, urea should be incorporated into the soil. It is also recommended to choose mineral fertilizers with a significant NO_3-N content, rather than other forms as $(NH_4)_2SO_4$. Management of organic fertilizers has to deal with different problems.^[22] In such cases, equipment that allows direct injection into the soil at sowing, at competitive cost or prompt (before 24 hr after application) plug-ins are effective. It is also useful to introduce some strategies in later cereal applications, such as dilution, to facilitate slurry infiltration into the soil to avoid losses.

Nitrification inhibitors may also be used, but do not seem to have any significant effect on NH_3 emissions; further research is needed, particularly under dryland and high pH conditions.

Organic fertilizers [manures, high in organic carbon (C) content] are also important in rainfed agriculture because of their effect in increasing organic matter and, thereby, improving physical soil properties as structure or water-holding capacity^[23] as well as biological ones. In arid and semiarid areas, organic fertilizers with high C-to-N ratios contribute modestly to maintain the organic N levels in the soil. Short-term N recycling occurs and, in some cases, can be significant in plant N uptake, but most of the added organic N remains in the soil organic N fraction.^[24]

University of Lleida researchers (Boixadera, Bosch, Sió, and Teira) have summarized^[25] how to improve agronomic efficiency of organic fertilizers in Mediterranean countries from a wide broad perspective.

Crop Management

Under Mediterranean conditions where NUE is linked to WUE,^[26] the choice of a winter or a summer crop and the cultivars are of the utmost importance. In semiarid and arid areas, barley is advantageous over wheat because of its shorter vegetative period, avoiding water stress and high temperatures during grain filling. Nevertheless, there are also differences, in the responses to drought, between barley cultivars.^[27] Decreasing soil evaporation through a fast initial growth of the crop also seems to be relevant because biomass accumulation takes place under low vapor pressure deficit.^[28] Adequate plant density would help to keep water and control excessive vegetative growth not just in cereals but also in legumes.^[29]

Tillage intensity is important in Mediterranean regions because as its intensity increases, it reduces soil water availability; it increases the oxidation of organic matter and the amount of N mineralized^[16] and erosion. Advantages of shifting from conventional to conservation tillage have been described^[30–32] in terms of soil aggregation, soil organic matter content, C sequestration, N conservation, microbial biomass C, enzymatic activity, and available water capacity. Nevertheless, the influence of tillage systems and the associated changes on soil properties on yields is very diverse. In arid and semiarid areas, conservation tillage has proved to be the best option to increase crop water use and WUE.^[33] In humid Mediterranean regions or in wet years in other subareas, yields and N concentrations in plants are less influenced by tillage systems and usually, with full availability of N fertilizers, conventional tillage gives higher yields.^[34] There is also a positive yield answer to N fertilization rates. In this case, no-tillage systems lose their economic interest in front of conventional tillage (the most productive), but minimum tillage remains economically advantageous.

Rotations

NUE can be evaluated in one cropping season or through all rotation.

Because of water stress, a significant portion can remain in soil in organic or inorganic forms than can be effectively used by the next crop by mineralization or directly, if water availability increases.

Crop rotations can be combined with fallow periods in Mediterranean arid areas. In arid and semiarid areas, it has been demonstrated^[35] that cereal production would be greater with annual cropping than with cereal–fallow rotation. One of the reasons could be that in conventional tillage systems, under fallow, residue cover is low (<10%). When no-till fallow is introduced in the rotation in semiarid environments, where surface is rewetted during the fallow period, the amount of residues plays an important role in improving soil water conservation^[36] as well as soil quality. No-till fallow strategies would theoretically allow to take advantage of mineralized N in low-input agricultural systems. It is well-known that N mineralization increases with the percentage of soil pores filled with water up to 60%.^[37] Nevertheless, a risk of leaching and also denitrification exists, with punctual summer rains. Additionally, since yields are low, straw production is low and recycled organic matter is low. If water is limiting, straw decomposition will be slow, but crop residues will help to control water and wind erosion. Thus, it may be concluded that fallows are not a reliable store for available N.^[38] If conservation tillage can be introduced, long fallowing is no longer recommendable in semiarid areas.^[39]

Legumes, in semiarid environments, are an alternative to fallow if their productivity is low and they produce relatively small biomass,^[40] thus reducing the impact on the next cereal crop. This cereal–legume rotation is an alternative to weed control and reduces the need for fertilizers, but increases complexity, and its economic advantages are little.

Cultivated pasture, except for humid areas, is considered very risky.

In humid areas, catch crops can be effective in reducing nitrate leaching potential by absorbing residual soil mineral N from earlier crops and available water.^[41] As the catch crop is buried, some of the absorbed N is returned to the soil, and it is available to the following crop.

Balanced nutrition is important to achieve optimum NUEs. One key element is phosphorus, playing a double role;^[42] first, it enhances root growth and thus increases the soil volume explored by roots, which, in turn, increases water available to the crop; second, it accelerates crop maturity by 10–14 days, which might allow the crop to escape to hot, dry conditions in the last part of the growing season.

CONCLUSION

In rainfed Mediterranean agricultural systems, rainfall and rainfall distribution are the most limiting factors for crop production. Increasing available water during the crop-growing period, through different agronomic strategies, will allow to obtain a positive yield answer to N fertilization,

increasing, at the same time, WUE. Thus, agricultural management must be inspired in the principle of minimizing each production resource that is needed to allow the maximum utilization of all other resources.^[43]

Agroclimatic analysis, soil characterization, choice of crops and cultivars adapted to water availability period, crop rotations, and the introduction of soil conservation practices, which allow to store water for critical periods and to match N availability to potential demand, are the major challenges.

Technological tools, such as the quantification of water and N_{min} available in soils, testing organic manure for nutrient and dry matter content, and better assessment of management practices as future nutrient application during crop growth for a site-specific area, are the main goals in order to increase the efficiency of N use in the agricultural systems of Mediterranean regions and to reduce environmental impacts in other systems.

Also, a good standard education is needed, for land managers, to face these challenges on complexity management, in a more competitive and open agricultural market.

Metal—Clay Interactions

Dean Hesterberg

Department of Soil Science, North Carolina State University, Raleigh,
North Carolina, U.S.A.

Abstract

Soils are vital for regulating the biological effects and mobility of metals in nature. Some metals such as potassium and calcium are essential nutrients for plants and animals, while others such as lead and mercury are potentially toxic. Therefore, a detailed understanding of the chemistry of metals in soils is essential for managing their agricultural and ecological impacts. Two soil components that are particularly important for regulating metal impacts are clays and organic matter. Clays consist of inorganic minerals in the fine particle-size fraction of soils (<0.002 mm particles) and may include associated organic matter. Modern concepts of metal interactions within soils evolved from the discovery in the mid-1800s that soils retain (bind) cations. Since then, researchers have applied a wide variety of analytical techniques and chemical principles to understand metal interactions within soils and with soil components.

INTRODUCTION

Most chemical elements are metals, and many of these occur naturally in soils. Metals usually occur as cations in soils. However, metal cations of higher charge such as chromium (Cr^{6+}) and molybdenum (Mo^{6+}) combine with oxygen to form stable molecules called oxyanions (CrO_4^{2-} and MoO_4^{2-}). The most abundant metals in mineral soils, aluminum (Al^{3+}) and iron (Fe^{3+} or Fe^{2+}), are mostly combined with oxygen anions (O^{2-}) into soil minerals such as aluminosilicates, Al hydroxides, and Fe oxides. Potassium (K^+), sodium (Na^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}) are abundant in all but highly acidic soils. Metals having a density greater than 5 g/cm^3 are called heavy metals. Except for manganese (Mn) and Fe, concentrations of heavy metals in non-contaminated soils are typically <100 mg/kg. In soils that are impacted by nuclear wastes, metals such as uranium, plutonium, cesium, and strontium are of concern.

Clays are especially important for binding metal ions because they have a high amount of surface area and the surfaces can be charged. Because oxygen constitutes, on an average, 60% of the atoms in soils, the surfaces of clay particles are typically dominated by oxygen atoms.^[1] Phyllosilicate (layer silicate) clay surfaces have a permanent negative charge because of minor substitutions of equivalently sized but lower-charged metal cations for more abundant cations within the crystal structure. The surfaces on the edges of aluminosilicate clay particles and surfaces of Fe-, Al-, and Mn-oxide minerals have a variable charge. This so-called pH-dependent surface charge from a loss or gain of hydrogen ions (H^+) on the surface oxygens as the concentration of H^+ (i.e., pH) in the surrounding water changes.

MECHANISMS OF METAL RETENTION BY CLAYS

Metal ions are retained by clays through: 1) adsorption; 2) surface cluster formation; 3) surface precipitation; 4) diffusion into an existing mineral structure; or 5) coprecipitation. The first three mechanisms occur at clay surfaces, the interface between clay particles and the surrounding water (aqueous solution). Diffusion results from a metal concentration gradient from the clay surface into the particle and occurs very slowly.^[2] Coprecipitation involves incorporation of metal ions into a clay structure as it forms.

Adsorption—Macroscopic Aspects

Adsorption is the net accumulation of a substance into a 2-D structure at the clay surface.^[3] Adsorption processes occur over time periods of seconds to days.^[4] The amount of a given type of metal ion adsorbed depends mainly on the total concentration of metal ions present, their affinity for the clay surfaces relative to the aqueous (water) solution, and factors such as pH and the presence of other (competing) ions. The concentration and affinity effects at constant pH and temperature are indicated by an adsorption isotherm, a plot of adsorbed vs. dissolved metal. Isotherms are classified according to their shape (Fig. 1). An H-curve reflects a high affinity of metal ions for the soil or clay, as is common for heavy metals at low concentrations. The H-curve can be fit mathematically with a Freundlich adsorption isotherm model.^[3] An L-curve suggests that the mineral particles have a high affinity for the metal ions at low concentration and a decreasing affinity, as the adsorbed metal concentration approaches the maximum adsorption capacity of the soil or clays.^[7]

Fig. 1 Classes of adsorption isotherms for metal ions in soils or clays. H-curve data are for <0.001 mm soil clay,^[5] adsorbed Cu values are scaled by a factor of 0.1, and data are fit with a Freundlich isotherm model. L-curve data^[6] are fit with a Langmuir isotherm model. For the S-curve data,^[3] adsorbed Cu values are scaled by a factor of 0.1 and fit with a smooth curve.

However, an isotherm does not reveal the molecular aspects of metal–clay associations, and metal retention mechanisms other than adsorption can also produce such a curve.^[8] The L-curve is fit mathematically with a Langmuir or Freundlich isotherm model.^[3] One explanation of an S-curve is that the presence of a metal-binding agent in the aqueous solution such as dissolved organic matter competes with the surfaces for the metal ions. As the total metal concentration increases, the capacity of the dissolved agent to bind metals is exceeded and adsorption increases.^[3]

Typical pH dependence of metal-ion adsorption on oxide minerals is illustrated in Fig. 2. With increasing pH, metal-cation adsorption increases and metal oxyanion adsorption decreases. These trends are related to the pH-dependent surface charge (Fig. 2). However, shifts in the adsorption curves along the x-axis for different metal cations added at the same level suggest that metal–clay interactions other than electrostatic attractions between the surface and oppositely charged ions are important. Heavy metal binding on such pH-dependent surfaces is strong under favorable pH conditions. Therefore, adsorption is not affected much by the presence of weakly bound cations such as Na⁺ and K⁺. Adsorption of heavy metal cations on permanent charge sites of phyllosilicate minerals is usually weaker than that on pH-dependent surfaces,^[2] so other cations more effectively compete for adsorption sites through a process called cation exchange.

Fig. 2 Effects of pH on the adsorption of metal cations (Cu²⁺, Pb²⁺, Zn²⁺, and Ni²⁺) and oxyanions (MoO₄²⁻ and CrO₄²⁻) on the Fe-oxide mineral goethite (α-FeOOH). The generalized number of protons and charge on reactive surface oxygens (e.g., >Fe–OH₂⁺) at different pH ranges assumes that the goethite particles have no charge at pH 7.8.^[7] Cation data^[9] (added metal: 20 mmol/kg goethite), molybdate data^[10] (added metal: 300 mmol/kg goethite), and chromate data^[11] (added metal: 0.6 mmol/kg goethite).

Adsorption—Molecular Mechanisms

On a molecular scale, three mechanisms of metal-ion adsorption are distinguished: inner-sphere surface complexes, outer-sphere surface complexes, and diffuse layer ions (Fig. 3). Inner-sphere complexation, also called chemisorption, involves metal bonding directly to atoms at the clay surface as one or more water molecules that

Fig. 3 Schematic illustration of molecular-scale mechanisms of metal cation (Cu²⁺, Mg²⁺, and Na⁺) oxyanion (MoO₄²⁻) adsorption on a goethite surface.

Source: Adapted from Alcacio, Hesterberg, et al.^[12] ©2001.

surround the dissolved ion are lost. A metal cation would bond directly to a surface oxygen that has lost its associated hydrogen ion (H^+). An oxyanion would bond through its own oxygen to the metal ion in the material that lies one atomic layer behind the surface oxygen that replaces (Fig. 3).^[2,3,7] As such, metal cations and oxyanions may compete for the same surface sites. Chemisorption involves a combination of covalent (electron sharing) and ionic (electrostatic) bonding. Outer-sphere surface complexes and diffuse ions are primarily bound to the surface through electrostatic attractions between the ions and oppositely charged surface sites. Outer-sphere surface complexes involve weaker binding of the metal ion directly on the clay surface but with water molecules positioned between the ions and the surface. Diffuse layer ions are not located directly on the surface but are moving about within a region called the diffuse double layer that extends nanometer-scale distances from the surface. Conceptually, the diffuse double layer exists because of the opposing forces of electrostatic attraction of ions to the charged surface and diffusion of the accumulated ions away from the surface.

Metal-cation adsorption on clays is modified by adsorbed organic matter. Adsorption involving interactions between clay surfaces, metal ions, and organic matter may consist of either the metal-ion bridging between the clay and the organic matter (Type A ternary complex) or the metal-ion adsorbing to the organic matter that is adsorbed on the clay surface (Type B ternary complex).^[12]

Surface Clusters and Surface Precipitates

With increasing concentration of adsorbed metal, metal ions may cluster together on the clay surface and form a 3-D structure comprising metal cations and hydroxyl anions (OH^-).^[8,13] As metal concentration on the surface increases, these surface clusters may grow into a surface precipitate that entirely covers the surface.

Coprecipitation

Metal ions can be incorporated into the bulk clay structure by a process called coprecipitation, which is the simultaneous precipitation (formation) of one compound in conjunction with another.^[14] When a mineral is formed, coprecipitation may involve the replacement of ions that are common to the mineral by metal ions of similar size and charge as the mineral forms. The substituted ions are dispersed as a minor component throughout the mineral. Another type of coprecipitation involves a metal accumulating as its own pure mineral phase encapsulated within a different pure mineral phase. A third type of coprecipitation involves an adsorption mechanism, whereby metal ions bind at surfaces of newly formed mineral particles, then become incorporated within the particles as they continue to grow.

CONCLUSION

Interactions between metals and clays in soils help regulate the plant availability of metals that are essential for agronomic crop growth, while affecting the mobility and environmental impacts of potentially toxic heavy metals. Because soils comprise a complex mixture of clays, organic matter, coarse-grained particles, water, air, and biological entities with properties that change both in space and time, accurately predicting chemical reactions and long-term fate of metals in a given soil is challenging.

Microbial Biomass: Measurement

K.R. Islam

S.R. Wright

Ohio State University South Centers, Piketon, Ohio, U.S.A.

Abstract

Common and new methods were discussed, including their advantages and disadvantages. Over the years, the indirect methods have been more widely used compared to direct methods for simple, rapid, and precise measurement of soil microbial biomass (SMB). Among the indirect methods, chloroform fumigation incubation has been used as a baseline for calibrations and correlations for other methods. Extraction methods, in particular the microwave soil extraction, are gaining increasing acceptance for their simplicity, rapidity, and precision in determining SMB. No method is universally accepted because of various limitations. Consequently, there is a demand for further improvement in SMB measurement

INTRODUCTION

Soil microbial biomass (SMB) is an active component of the terrestrial ecosystem that regulates many critical functions and properties related to soil and environmental qualities. The functions and processes include source-sink in nutrient cycling, decomposition of organic residues, structural stability, and indicator of soil pollution and bioremediation.^[1–3] No standard method for measuring SMB is available, but several widely differing approaches have been developed. Methods used for measuring SMB are briefly discussed.

DIRECT METHODS TO MEASURE SMB

In direct methods, microorganisms are determined by colony forming units counted on soil dilution series using most probable number (MPN) and/or by direct microscopic counting methods. In MPN method, soil samples are dispersed in a series of dilution to estimate population density based on the presence or absence of microbial cells.^[4] Thus, if microbial growth is observed in the 10^{-4} but not in the 10^{-5} dilution, the number of cells is estimated in between 10^4 and 10^5 .

The direct microscopic method involves dispersing a known amount of fresh soil in a known volume of water, or dilute agar media is smeared over a known area on a glass slide to count for microbial cells using fluorochromes. The measurement of SMB from cell dry weight and volume characteristics^[5] is as follows:

$$\text{Bacterial biomass}(\mu\text{g/g oven-dry soil}) = \text{NVB}^b 10^6 \quad (1)$$

where nitrogen (N) is the number of bacteria/g of oven-dry soil, V is the average volume of bacterial cell (μm^3), and B^b is the biomass/volume conversion factor ($0.22\text{--}0.33 \times 10^{-12} \text{ g}/\mu\text{m}^3$).

$$\text{Fungal biomass}(\mu\text{g/g oven-dry soil}) = \text{L}\Pi r^2 B^f 10^6 \quad (2)$$

where L is the mycelia length (in $\mu\text{m/g}$ oven-dry soil), r is the average radius of mycelia (μm), B^f is the biomass/volume conversion factor ($0.2\text{--}0.33 \times 10^{-12} \text{ g}/\mu\text{m}^3$).

Soil MPN method based on dilution is widely applicable to bacterial cell counting, but for fungi, it is only valuable for spore or other propagule counting. The direct microscopic method is a tedious procedure, and often yields result 10–100 times greater than the soil dilution techniques.

INDIRECT METHODS TO MEASURE SMB

In indirect methods, the SMB is assessed by using biochemical, chemical, and physical principles for determination of a particular cell constituent such as carbon (C), N, phosphorous (P), sulfur (S), adenosine triphosphate (ATP), and phospholipids of microbes.^[6–14]

Chloroform (CHCl_3) Fumigation Incubation (CFI) and Extraction Methods

CHCl_3 fumigation has been a reference method to determine SMB since it was first developed.^[9] The rationale for the CFI method is that the fumigant lysed the soil microbes and the resulting increase in carbon dioxide (CO_2) evolution from fumigated soil, compared to unfumigated soil,

over a 10-day incubation period at 25°C, is directly proportional to the amount of C in the SMB.^[9] The amount of released CO₂ is determined by absorption in 0.5 M sodium hydroxide (NaOH), followed by acid–base titration to calculate the SMB.

$$\text{SMB} = F_c/K_c \quad (3)$$

where F_c is the net flush of CO₂ from fumigated and unfumigated soils, respectively, during incubation, and K_c is a coefficient of 0.45.^[9]

In the CHCl₃ fumigation extraction (CFE) method, the postfumigated soil is extracted with suitable extractants for flush of C, N, P, and S compared to unfumigated soils.^[6] Soil extracts were analyzed for C, ninhydrin-reactive N, P, and S to calculate SMB.^[6,13]

$$\text{SMB} = 2.68V - 44.1 \quad (4)$$

where V is the net flush of C from fumigated and unfumigated soils, respectively extracted by neutral 0.5 M potassium sulfate (K₂SO₄).

$$\text{SMB} = 20.0 \times \text{NRN if soil pH is} > 5.0 \quad (5)$$

$$\text{SMB} = 35.3 \times \text{NRN if soil pH is} \leq 5.0 \quad (6)$$

Both CFI and CEF methods yield good estimates of SMB, but CHCl₃ is a biohazard. Also, the CFI method is affected by high organic matter content, organic amendments, low pH, and soil waterlogged conditions and is time-consuming and involves several steps.^[1,9] The CFE method is fast and useful where CFI does not work.^[6] A portion of the SMB may be insensitive to CHCl₃ fumigation.

Microwave (MW) Irradiation Incubation and Extraction Methods

The underlying principle of the MW irradiation method is to use non-thermal MW energy at 800 J/g oven-dried equivalent of field-moist soil in plastic tubes with punctured caps to disrupt the microbial cells and then incubate or extract the MW and unmicrowaved soils to measure flushes of C.^[8] In MW irradiation incubation method, both MW and unmicrowaved soils are incubated for 10 days in the dark at 25°C, and the flush of CO₂ is absorbed in dilute solution of NaOH followed by an acid–base titration to calculate the SMB.

$$\text{SMB} = \text{CO}_2 - C_{\text{MW}}/K_{\text{MI}} \quad (7)$$

where $\text{CO}_2 - C_{\text{MW}}$ is the net flush of CO₂ from MW and unmicrowaved soils, respectively, and K_{MI} is a coefficient of 0.341.

In MW irradiation extraction method, the MW soil is extracted for flush of C by neutral 0.5 M K₂SO₄ compared to unmicrowaved soil.^[8] An automatic analyzer

with ultraviolet (UV) persulfate oxidation and infrared (IR) detection, or rapid colorimetric^[8,15] or titrimetric method, is used to determine extracted C for the SMB measurement.

$$\text{SMB} = C_{\text{EXTMW}}/K_{\text{ME}} \quad (8)$$

where C_{EXTMW} is the net flush of C from MW and unmicrowaved soils, respectively, and K_{ME} is the extraction coefficient (0.213) of the SMB.^[8]

The MW irradiation method is an alternate approach to CFI and CFE methods for rapid, precise, safe, and reliable measurement of SMB.^[8] This method is very economical. To avoid the release of nonbiomass C from soil, the MW oven has to be calibrated before use.

Rehydration Method

Rewetting of air-dry soils with dilute salt solution or water is the basis for the rehydration method for determining SMB.^[16,17] Upon rehydration, the desiccated microbial cells in air-dried soils are disrupted and they release intracellular C compounds. The extracted C is analyzed by a rapid potassium dichromate oxidation method to determine the SMB content.

$$\text{SMB} = E_c/0.23 \quad (9)$$

where E_c is the net flush of 0.25 M K₂SO₄ extracted C from air-dried and field-moist soils, respectively, and 0.23 is the extraction coefficient.^[17]

The rehydration method is a simple procedure for SMB determination that does not use hazardous chemicals, although prolonged air-drying of soil often releases non-biomass C. A portion of the SMB may be insensitive to air-drying.

Freeze-Dried Soil Extraction Method

The principle of the method is that extraction of freeze-dried soils with either 0.5 M K₂SO₄ or 0.5 M sodium bicarbonate (NaHCO₃) releases cytoplasmic C compounds from desiccated and disrupted microbial cells.^[7] The extracted C is analyzed by a rapid colorimetric method^[15] to calculate the SMB contents.

$$\text{SMB} = C - K_2\text{SO}_4/0.152 \quad (10)$$

$$\text{SMB} = C - \text{NaHCO}_3/0.257 \quad (11)$$

where $C - K_2\text{SO}_4$ and $C - \text{NaHCO}_3$ are the net differences in C extracted by 0.5 M K₂SO₄ and NaHCO₃ from freeze-dried and field-moist soils, respectively.

This is a precise, reliable, and safe method for measuring SMB but it requires trained personnel and sophisticated equipment.

Adenosine Triphosphate Extraction Method

The principle of this method is that, by using suitable reagents, soil microbial cells are rapidly disrupted. This is followed by stabilization of ATP with deactivating synthesis and degradative enzyme processes, and extraction of ATP from the soil matrix. Then, using luciferin–luciferase light reactive system, SMB contents can be calculated.^[18,19]

$$1 \mu\text{g ATP} = 250 \mu\text{g of SMB} \quad (12)$$

As ATP is rapidly degraded during extraction and adsorbed by soil constituents, SMB measurement is often uncertain because of storage conditions, season of collection, low and irregular recovery, and weak correlation to SMB measured.^[1]

Phospholipid Fatty Acids Extraction Method

This method is based on extraction of phospholipid fatty acids (PFLA) from soil microbial cell membranes via suitable extractants.^[11,14] The lyophilized soil is extracted with the single-phase CHCl_3 – CH_3OH –buffer system, followed by analysis of PFLA by a capillary gas chromatography (GC) with flame ionization detection to SMB.^[14]

$$1 \text{ nmol PFLA/g soil} = 2.4 \mu\text{g SMB} \quad (13)$$

Extracts are easily analyzed to identify the different PLFAs for the determination of SMB,^[5] but this is a time-consuming, complex, and expensive method.

Substrate-Induced Respiration (SIR) Method

The SIR method, which was first reported by Anderson and Domsch,^[10] utilizes the initial change in the soil respiration response as a result of adding glucose or sucrose and nutrients. The SMB is calculated from the maximum initial respiratory response (MIRR) measured at 22°C, as follows:

$$\text{SMB} = (40.04 \text{ MIRR}) + 0.37 \quad (14)$$

where MIRR is $\mu\text{L CO}_2/\text{g soil}$.

This is a fast method to measure SMB but may often overestimate by measuring the glucose responsive active portion of the SMB. The use of glucose may shut down the metabolism of other microbes. The SIR method requires a GC to measure evolved CO_2 .

UV SPECTROSCOPIC METHOD

This technique is a rapid and inexpensive method to estimate SMB based on the near-UV light absorption of certain molecules (nucleic acids/nucleotides) of microbial cells

extracted from CHCl_3 fumigated soils.^[3] UV absorbance at 280 nm is significantly correlated to SMB measured by CHCl_3 method as follows:

$$\text{SMB} = 21,747 \times E_{280 \text{ nm}} \quad (15)$$

Although a fast and simple method to determine SMB, this process uses CHCl_3 . The results are often compromised by soil colloidal interferences and electrolyte precipitation.^[3]

CONCLUSION

Common and new methods were discussed, including their advantages and disadvantages. Over the years, the indirect methods have been more widely used compared to direct methods for simple, rapid, and precise measurement of SMB. Among the indirect methods, CFI has been used as a baseline for calibrations and correlations for other methods. Extraction methods, in particular the MW soil extraction, are gaining increasing acceptance for their simplicity, rapidity, and precision in determining SMB. No method is universally accepted because of various limitations. Consequently, there is a demand for further improvement in SMB measurement.

Microbial Communities

K.R. Islam

S.R. Wright

Ohio State University South Centers, Piketon, Ohio, U.S.A.

Abstract

The soil is a complex and dynamic component of the terrestrial ecosystem with a diverse community of microbes dominated by bacteria, fungi, actinomycetes, and algae. The microbial community is vital to the cycle of life on earth. They incorporate plant and residues into the soil and digest them, returning carbon dioxide to the atmosphere, where it can be recycled through higher plants. Simultaneously, they release nutrients during decomposition of organic residues and form soil organic matter, which is vital for soil quality. With the diversity in a soil ecosystem, many types of community interactions are possible, including parasitism, competition, and symbiosis.

INTRODUCTION

The soil, a complex and heterogeneous component of terrestrial ecosystems, sustains an immense number and diversity of microorganisms, which require much more study. Actually, less than 1% of the soil microorganisms have been cultured, identified, and characterized in the soil ecosystem. Soil microorganisms, prokaryotic and eukaryotic, spend all or part of their lives in the soil environment.^[1,2] These microorganisms live together by interacting with each other and with other organisms in the soil.

The soil microbial community presents a complex and variable association among the different levels of biological organization, which encompasses genetic variability and the richness and relative evenness in communities. There is a growing interest in the relationships among ecosystem diversity, structure, and function. A number of theories have been formulated on how microbial species composition and diversity relate to the functional capability of the terrestrial ecosystem.^[3] It has been suggested that enhanced microbial species diversity is beneficial to ecosystem function.^[4,5] Others suggest that the properties of an ecosystem depend more on the functional capabilities of a particular microbial species than on the total number of species.^[6–8]

COMPOSITION OF SOIL MICROBIAL COMMUNITIES

The soil contains billions of organisms representing nearly every phylum.^[9] Microbial communities are the most complex and diverse group of soil organisms, ranging in size from 0.5 to 5.0 μm , which consists predominantly of bacteria, fungus, actinomycetes, and lichens.^[2,10] A simplified,

general classification of soil microorganisms is presented in [Table 1](#).

Soil bacteria are single-celled, prokaryotic organisms in various shapes and sizes (0.5–5 μm). They are perhaps the most complex and diverse group of soil microorganisms (about 20,000 different species per gram of soil) and are adapted to most environments.^[2,10] In general, bacteria are not energy-efficient organisms in soil (only about 20% of the organic substances decomposed may become bacterial tissue).^[11]

Soil fungi are eukaryotic organisms that may form visible macroscopic structures in soil. Fungi comprise an extremely diverse group of microorganisms with tens of thousands of species present in the soil. Although they are usually in somewhat smaller numbers than bacteria, fungi dominate the biomass and metabolic activity in many soils because of their relatively large size and branching. Fungi are energy-efficient organisms in soil (30–50% of the organic substances decomposed may become bacterial tissue).^[11]

Like the fungi, actinomycetes are filamentous and often profusely branched cells, although their mycelia threads are much smaller than those of fungi. Actinomycetes were previously classified with the fungi; however, they are now classified as bacteria. They have no nuclear membrane and often dissociate into spores that closely resemble bacterial cells. We will consider them separately because of the unique roles they play in the soil compared to bacteria.^[2,10]

Although actinomycetes develop best in moist, warm, well-aerated soil, they are functionally important in arid-region, salt-affected soils.

Algae are eukaryotic cells ranging in size from 2 μm to 20 μm . Several hundred algal species have been identified in soil, but only a small number of species are prominent throughout the world. Most algae grow best

Table 1 Relative numbers and biomass of microbial species at 0–15-cm depth of soil.

Microorganisms	Number per gram of soil	Biomass (g/m ²)
Bacteria	10 ⁸ –10 ⁹	40–500
Actinomycetes	10 ⁷ –10 ⁸	40–500
Fungi	10 ⁵ –10 ⁶	100–1500
Algae	10 ⁴ –10 ⁵	1–50

Source: From Adu & Oades.^[11]

under moist to wet conditions, but some thrive in hot or cold environments.

DETERMINATION OF SOIL MICROBIAL COMMUNITIES

A number of techniques have been developed to culture, identify, and characterize microbial communities. Such methods characterize substrate utilization by *in situ* microbial communities or by part of the community that is culturable in Biolog GN microplates, which are used to produce community-level physiological profiles. As no single universal method is available to determine the whole microbial community, a combination of methods was developed over time. Methods to analyze microbial community structure and function have been generalized for dominant groups such as bacteria and fungi. Population may be determined through direct counting,^[12,13] specific cell component analysis,^[14–16] substrate-induced respiration,^[17] chloroform fumigation and microwave incubation, and extraction methods^[18–20] and DNA analysis.^[21] The use of molecular technology, including polymerase chain reaction amplification, cloning, and sequence analysis of the 16S subunit of ribosomal RNA, is becoming a much more common means of estimating the composition of the bacterial community.^[21]

FACTORS AFFECTING SOIL MICROBIAL COMMUNITIES

The soil ecosystem comprises a variety of microhabitats with different physicochemical gradients and discontinuous environmental conditions that are influenced by the physical and chemical properties of the soil, the type of vegetative cover, the climate,^[22] and the soil-crop management practices. The structure and function of soil microbial communities reflect between hosts of biotic and abiotic components of the terrestrial ecosystem.

Amount, Quality, and Placement of Organic Residues

Organic carbon (C) compounds, from plant residues and soil organic matter, are used as energy and food sources by

the heterotrophic microorganisms in soil. The quality of the plant litter reflects the biochemical composition of the substrates and the physical availability of the substrates to the microorganisms.^[23] Bacteria tend to respond most rapidly to additions of simple C compounds such as starch, sugars, and amino acids, while fungi and actinomycetes dominate if complex C compounds such as cellulose and more resistant lignin materials are available.^[24] In addition, if organic residues are deposited on the soil’s surface (under conifer forest and no-till systems), fungi dominate the microbial activity. Bacteria commonly play a larger role if the substrates are mixed into the soil, as by earthworms, root distribution, and tillage.^[25]

Soil Moisture, Aeration, and Temperature

While most microbes are aerobic and use oxygen as the electron acceptor in their metabolism, some microbes are anaerobic and use chemical compounds with combined oxygen other than gaseous oxygen. Facultative microbes use either aerobic or anaerobic forms of metabolism. Usually, these three metabolisms simultaneously occur in different habitats within a soil. Soil microbial activity is generally greatest when temperatures are within 20–40°C. The warmer end of this range tends to favor actinomycetes. Except for certain cryophilic species, most microorganisms cease metabolic activity below about 5°C, a temperature sometimes referred to as biological zero.^[2,10]

Soil Reaction

Soil reaction is a factor in determining which specific microorganisms dominate and function in a particular soil. Although some bacterial species may thrive in any chemical condition of the soil, near-neutral pH results in the largest and most diverse composition of bacterial populations. Acidity enhances soil fungi activity. The acidity effect explains why fungi tend to dominate in forested soils while bacterial biomass generally dominates over fungi in slightly acidic subhumid to semiarid prairie and rangeland soils.

Management Practices

Type, timing, and degree of tillage affect microbial processes by placing plant residues on soil or in soil contact, exposing native and protected C, and by altering soil aeration, moisture, and temperature conditions.^[26,27] Once in the soil, plant residues serve as energy and C sources for heterotrophic organisms.^[28] In general, greater additions of plant residue to soil under conservation management practices are almost always followed by a flush of biological activities, coinciding with an increase in microbial biomass and metabolic activity.^[27] The incorporation of easily decomposable plant residues with relatively low C:nitrogen (N) ratio is a unique feature of legume-based cropping

system, which enhances soil biological processes compared to conventional systems.

ROLE OF SOIL MICROBIAL COMMUNITIES

The processes and functions of the terrestrial ecosystem are regulated by the activities of soil microorganisms. Some of the important ecological functions related to the activities of the microbial community are litter decomposition, nutrient cycling, bioremediation, C sequestration, and improvement of the physical properties of the soil.

Litter Decomposition and Nutrient Availability

Litter decomposition is perhaps the most significant contribution of the soil microbes in terrestrial ecosystem. Through this process, the complex chemical compounds in dead leaves, roots, and other plant tissues are broken down into simpler chemical compounds, converting organically held nutrients into mineral forms available for renewed plant uptake. The release of N from decomposition of organic residues is a prime example. Soil microbes also assimilate wastes from animals and other organic materials added to soils. As a by-product of their metabolism, microbes synthesize new compounds, some of which help stabilize soil structure, while others contribute to formation of soil organic matter and improve soil quality over time.^[27]

Inorganic Nutrient Transformations

The transformation of inorganic nutrient elements and compounds is of great significance to the ecological functions of the soil systems, including plant growth. Nitrate, sulfate, and, to a lesser degree, phosphate ions are present in soil primarily because of microbial activities. Bacteria and fungi assimilate some of the N, phosphorous (P), and sulfur (S) in the organic materials they digest. Excess amounts of these nutrients may be excreted into the soil system in inorganic forms usable either by the bacteria and fungi themselves or by other organisms that feed on them. In this process, organically bound forms of N, P, and S are converted into inorganic forms that are available to higher plants. Likewise, the solubility and availability of the other essential elements, such as iron (Fe) and manganese (Mn), are largely determined by microbial activities in soil. In well-drained soils, these elements are oxidized by autotrophic microorganisms to their valence states, in which forms they become quite insoluble, which keeps Fe and Mn mostly in non-toxic forms even under fairly acidic conditions. Microbial oxidation also controls the potential for toxicity in soil contaminated with selenium, arsenic, and chromium compounds.

Biological N Fixation

N is one of the primary nutrients for plant growth. Atmospheric N₂ is an inert gas that cannot be directly used by higher plants. Biological N fixation is one of the most important microbial processes in soils. Actinomycetes of the genus *Frankia* fix major amounts of atmospheric N in forest ecosystems; cyanobacteria are important in flooded rice systems, wetlands, and deserts; and rhizobia are the most important group for the fixation of gaseous inert N in agricultural soils.^[10] By far, the greatest amount of N fixation by these microorganisms occurs in root nodules or in other close associations with plants. Worldwide, every year, microbes in soils fix enormous quantities of atmospheric N into forms usable by higher plants.^[2]

Soil Aggregate Stability and Carbon Sequestration

Aggregate structure is a key biologically mediated soil property that results from close associations of fungal hyphae with plant roots and from release of low molecular weight organic acids associated with clays, metals, and microaggregates.^[29] In addition to C retention through efficient cell assimilation, extensive fungal hyphal associations with plant roots can contribute to protect and accumulate C by enhancing macroaggregation through physical enmeshing of soil microaggregates or releasing extracellular polysaccharide as binding agents or stabilization through complex association with metals as microaggregates.^[30,31]

The microbially derived decomposition products cement primary particles, organic debris, and microaggregates together to form and stabilize macroaggregates.^[32] An enhanced physical protection of fragmented organic debris and microbial decomposition products within macroaggregates is an important mechanism enabling the soil C accumulation.^[32] These mechanisms, in turn, increase the proportion of C in soil aggregates that is physically protected from microbial decomposition and protects soil from accelerated soil erosion.^[27]

Breakdown of Toxic and Xenophobic Compounds

Many organic compounds toxic to plants or animals find their way into the soil. Some of these toxins are produced by soil microbes as metabolic by-products; some are applied as agrochemicals to kill pests and insects and to control weeds; and others are deposited in the soil because of environmental contamination. If these compounds continuously accumulate, they would do enormous ecological damage. Some toxins are xenophobic compounds foreign to biological systems, and these may resist attack by commonly occurring microbes. Soil bacteria and fungi are especially important in helping maintain a non-toxic soil environment by breaking down toxic compounds.

Plant Protection and Diseases

Certain soil microbes protect higher plants from invasion by soil parasites and pathogens; however, others attack plant roots. According to several research studies, many plants that are resistant to soilborne diseases have camouflaged rhizosphere,^[10,33] that is, although the rhizosphere of these resistant plants is enriched in microbial numbers, the types of microbes are more similar to those in the bulk soil than in the rhizosphere of disease-susceptible plants. Having a rhizosphere microbial community that is similar to the bulk soil community may make the rhizosphere of these plants less identifiable to pathogens.

Beneficial rhizobacteria have an intriguing mode of action called induced systematic resistance, which prevents infection of plants by diseases, insects, or pests, both above and below ground. In many cases studied so far on crops, the resistance-inducing organism was *Pseudomonas* or *Serratia* bacterium.^[10,33] This mechanism was shown to effectively reduce damages by numerous fungal, bacterial, and viral pathogens, and several leaf-eating insect pests.^[33]

Disease infestations occur in great variety and are induced by many different soil microorganisms. Among the microorganisms, bacteria, actinomycetes, and fungi are responsible for most of the common soilborne diseases of crops. Examples of such diseases are wilts, damping-off, root rots, clubroot of cabbage, and blight of potatoes.

INTERACTIONS OF SOIL MICROBIAL COMMUNITIES

With the diversity in a soil ecosystem, many types of interactions of the microbial community with plant roots and other soil organisms, and between several microorganisms, are reported. The most important associations are given below.

Antagonistic Interactions

Among the antagonistic interactions, parasitism, where one species resides within another, and predation, where one species actively pursues another, are deleterious associations of two microbial populations in the sense that one organism gains an advantage at the expense of another. Bacteria that prey on other bacteria are active in soil ecosystems.^[2,34,35] Protozoa and nematodes^[36] that feed on bacteria are also active in the soil ecosystem. This can have a significant effect on population.^[37] Parasitism of *Pythium coloratum*, the fungi responsible for cavity-spot disease in carrots, by actinomycetes has been reported.^[38]

Competition Interactions

Competition occurs when the growth of one species or community is suppressed by another species or community that more effectively obtains a limiting resource, or when one species or community is inhibited by the products of a second species or community. Limiting resources may be electron acceptors,^[37,38] mineral resources,^[39] host organisms,^[40] and carbon sources.^[41]

When fresh organic residues are added to the soil, the vigorous heterotrophic soil microbes compete with each other for this food resource. If simple compounds such as sugars, starches, and amino acids are available in the organic residues, the bacteria initially dominate because of their rapid growth and preference for simple compounds. As these simple compounds are metabolized, the fungi, and particularly the actinomycetes, become more competitive in soil by altering habitat conditions. Certain microbes alter the acidity level in their vicinity to the disadvantage of competitors. Others produce strong bonding compounds to protect the food source.

Production of antimicrobial compounds may also limit the development of other microbes. The potato soft-rot pathogen, *Erwinia carotovora* subsp. *atroseptica* (van Hall) Dye, is controlled by the production of the antibiotic 2,4-diacetylphloroglucinol by *Pseudomonas fluorescens* (Trevisan) Migula F113.^[42] However, the production of antibiotics does not eliminate other possible mechanisms of action. It has been reported that non-pathogenic strains of *Agrobacterium* prevent expression of disease rather than killing the pathogens.^[43]

Mutualistic Interactions

A mutually beneficial relationship between and among microorganisms is common in soil. The most familiar is the relationship between leguminous plants and rhizobia to fix atmospheric N. Symbiotic relationships are also found between populations of N-fixing communities and non-fixing communities,^[44] and *Rhizobium* and arbuscular fungi.^[45] One of the most ecologically and economically important activities of soil fungi is the mutually beneficial association between certain fungi and the roots of higher plants. This association is called mycorrhizae, a term meaning “fungus root.” In natural ecosystems, especially in degraded sites, many plants are quite dependent on mycorrhizal relationships and cannot survive without them; however, both parties benefit from such relationship.

The microbiotic crusts are intricate living systems in arid rangelands. They consist of mutualistic associations that usually include algae or cyanobacteria along with fungi, mosses, bacteria, and liverworts.^[10] The presence of microbiotic crusts is considered a sign of healthy or recovering ecosystems.

CONCLUSION

The soil is a complex and dynamic component of the terrestrial ecosystem with a diverse community of microbes dominated by bacteria, fungi, actinomycetes, and algae. The microbial community is vital to the cycle of life on earth. They incorporate plant and residues into the soil and digest them, returning carbon dioxide to the atmosphere, where it can be recycled through higher plants. Simultaneously, they release nutrients during decomposition of organic residues and form soil organic matter, which is vital for soil quality. With the diversity in a soil ecosystem, many types of community interactions are possible, including parasitism, competition, and symbiosis.

Micromorphology and Soil Quality

Ahmet R. Mermut

Department of Soil Science, University of Saskatchewan, Saskatoon,
Saskatchewan, Canada

Abstract

Soil micromorphology has numerous applications to soil quality assessment. These include the assessment of soil pores, aggregates, crusting, biology including ecosystems and faunal activity, soil chemistry, environmental chemistry, and mineralogy. Whereas numerous advances were made in the 1970s and 1980s, there is a vast scope for the use of these techniques.

INTRODUCTION

The book *Micropedology*^[1] and a large number of publications have induced many people to practice soil micromorphology since 1950s. Major areas where micromorphological analyses were used to determine soil quality in the 1970s and 1980s were in soil physics (soil pores, aggregates, and crusting), biology including ecosystems and faunal activity, soil chemistry, environmental chemistry, and mineralogy. These applications were made possible by the advent in computer science and development of image analyses technologies^[2,3] for better quantification of soil features.

So far, quantitative data were obtained from two-dimensional measurements, on the basis of aerial percentage. As is performed in stereology, 2-D measurements are extended to volume percent by the Delesse principle; i.e., aerial percentage is an unbiased estimate of volume percentage.^[4]

SOIL PORES, AGGREGATES, TILLAGE, AND SOIL CRUSTING

Of all the physical measurements, pore size distribution is the most pertinent parameter for plant growth.^[5] Soil porosity is dynamic^[6] and exhibits a high degree of physical anisotropy. Primary focus in porosity studies has been on the measurement of total porosity and shape and size classes of pores. It was discovered that the measurements of porosity itself are not sufficient unless it is coupled with other soil physical, biological, and chemical analyses.^[7] Despite the difficulties, attempts were made to measure the full spectrum of pore sizes, from pore diameters in the order of centimeters to those of nanometers.^[8]

Application of micromorphology in soil structure and aggregates gained considerable momentum in the 1960s, 1970s, and 1980s (Fig. 1).^[9–12] Impact of tillage implements, including zero tillage and crop rotation on soil

structure, received considerable attention.^[13] This was followed by studies dealing with surface crusting and sealing.^[14–16] These studies suggested that the susceptibility of soils to surface crusting and sealing depends on a combination of several physical and chemical properties of soils (Fig. 2).

Several investigators have studied the effect of different kinds of tillage operations on soil porosity and structure (Table 1).^[17–19] The data led to insight of different properties and functions of soil structure and porosity. Pagliai^[20] suggested that conservation or zero-tillage practices, when compared with conventional tillage, maintain soil structure and optimize soil porosity. Several workers have attempted to directly quantify porosity using thin sections or impregnated and polished soil blocks.^[21–23] Yet the influence of tillage operations on soil porosity is not completely appreciated.

Mermut et al.^[24] used image analyses to evaluate the impact of deep ripping and paraplowing on soil porosity in two lacustrine soils in Saskatchewan. Deep ripping increased soil porosity in the surface horizon, whereas the influence of paraplowing was evident up to 30–60 cm depth (Fig. 3). Two tillage methods used in this study increase large planar voids, but non-planar intra-aggregate voids were not influenced by tillage. It has been suggested that pores should be measured more frequently and over a long time, so that a clearer picture of the dynamics is better understood.

Mineralogy of clay sized particles and rainstorm characteristics are among the major factors that determine the nature of soil sealing.^[25] Southard et al.^[26] found that soil material suspended in water containing electrolytes resulted in less dense and more porous crust. Several crust types were identified.^[15,16,27]

SOIL FAUNA

The impact of organisms on the function and quality of soil is an important area of research.^[28,29] By using interactive image analysis system and a video camera,

Fig. 1 (A) Thin section micrograph showing interconnected simple and compound and (B) packing void (interaggregate pores) under partially crossed polarized light (p = pores; q = quartz; c = soil aggregates). micromorphologists can measure the size and shape of fecal pellets of animals observed in soil thin sections. Such an analysis can determine the possible ecological significance of the fecal pellets of animals in soils, and the data generated are essential to the protection, use, and management of soils and forests (Fig. 4).

SOIL ORGANIC MATTER

Micromorphologists are also interested in soil organic matter and its dynamics.^[30] Several textbooks and articles were published by Kubiena^[31] between 1938 and 1970 on soil

organic matter, mainly to determine the function and turnover of organic matter in soils. Submicroscopic techniques were also used to study organic matter *in situ* by histochemical staining methods in terms of organic matter function in ecosystem.^[32] This is an important and high-priority area of research.

MICROCHEMISTRY AND SUBMICROSCOPIC STUDIES

Pioneering works in undisturbed *in situ* microchemical analyses of polluted soils have been carried out on heavy metals.^[33] When coupled with image analyses, these techniques provide not only the location, but also quantity and distribution of the pollutant in soils. With the help of the new instrumentation, such as synchrotron, revolutionary scientific research can be performed.

CONCLUSION

Soil micromorphology has numerous applications to soil quality assessment. These include the assessment of soil pores, aggregates, crusting, biology including ecosystems and faunal activity, soil chemistry, environmental chemistry, and mineralogy. Whereas numerous advances were made in the 1970s and 1980s, there is a vast scope for the use of these techniques.

Abstract

Nutritional health and well-being of humans are entirely dependent on plant foods either directly or indirectly. There are silent epidemics of vitamin and mineral deficiencies affecting people in many developing countries. Micronutrient deficiency is affecting over 2 billion people worldwide. The malnutrition is the result of insufficient intakes of micronutrients through staple foods. Deficiency of zinc (Zn), iron (Fe), manganese (Mn), copper (Cu), boron (B), and molybdenum (Mo) has been observed in 49%, 12%, 5%, 4%, 33%, and 13% soils of India, respectively. Among micronutrients, Zn is highly deficient micronutrient and the deficiency of Zn in soils is further expected to increase from 49% to 63% by the year 2025. Low availability of micronutrients in soils such as Zn, Cu, and Mo showed a good relationship with micronutrient malnutrition but this relationship was not so evident for Fe. Diversification of cropping system and fertilization for meeting nutritional requirement is essential for reducing malnutrition. This review focuses on causes and amelioration of micronutrients deficiency in human diet by manipulating the agricultural practices that may result in supplying required intake of vitamins and minerals for better health and productivity of humans and animals.

INTRODUCTION

Nutrient sufficiency is the basis for good health, productive, and longevity of life. Primary aim of agricultural productivity is to ensure food security and safety. There is little concern on nutritional value or health promoting qualities of food produced. If agricultural systems fail to provide enough food diversity, quality, and quantity to satisfy all the nutrients essential to human life, health of people will deteriorate and national development efforts will stagnate. Although major emphasis of nutritionist has been on protein energy malnutrition, World Health Organization (WHO)^[1] data show that deficiency of micronutrients is far more severe. Approximately 1.7 million (2.8%) of deaths worldwide are attributed to micronutrients deficiency caused by lower consumption of fruits and vegetables that is regarded as top 10 selected risk factors for global mortality (WHO^[2]). These deficiencies affect the population of Europe and more severely in the transition countries of Eastern Europe, the former Soviet Union, and countries of Central Asia. World Bank has estimated that most affected malnutrition countries may lose up to 2–3% per year of their gross domestic product.

According to WHO, iron (Fe), zinc (Zn), vitamin A (beta-carotene), selenium (Se), and iodine (I) are the most prevalent trace element deficiencies in living being. Population affected by their deficiencies showed low productivity, decreased cognition, learning disability among children, lower worker productivity, increased morbidity and mortality rates, impact on immune system, and high health-care costs.^[3] Pregnant women lacking key nutrients not only increase the risks of death during childbirth but also the risk not to provide proper nutrients to her infant child.

Feeding the world's poor with biofortified seeds/edible parts can significantly improve the content of nutrients in the target population. Challenge ahead lies in enhancing substances (e.g., ascorbic acid, S-containing amino acids, etc.) that promote micronutrient bioavailability or decrease antinutrient substances (e.g., phytate, polyphenolics, etc.) that inhibit micronutrient bioavailability. Fighting Fe-deficiency-created anemia through the use of transgenic and meeting the Zn demands of human heart through the Zn-fortified food grains are the immediate challenges in micronutrient research in soils and plants.

Based upon Zn and Fe deficiency in soils, there is no standard method of relating it to their suboptimal levels in human.

While Zn deficiency can be alleviated by increasing Zn density in food crops by Zn fertilization, such possibilities for managing Fe deficiency are economically unfavorable. Hence, soil conditions and agronomic practices are conducive to be the incidence of micronutrient deficiencies in plants. The production of low micronutrient foodstuff has created concern about nutritional deficiency-related health hazards especially in poor masses of the society in developing countries.^[4] It is imperative to initiate studies on such global problems with due attention.

MAGNITUDE OF MICRONUTRIENT DEFICIENCIES IN SOILS

According to Food and Agriculture Organization estimates, 50% of world's soils growing cereal crops are Zn deficient. In India, analysis of 250,000 surface soil samples collected from arable soils revealed the predominance of Zn deficiency in divergent soils. Out of these samples, 49%, 12%, 5%, 4%, 33%, and 13% soils are tested to be deficient in Zn, Fe, Mn, Cu (DTPA – Diethylene triamine penta acetic acid extractable), B (hot water-soluble) and Mo (Ammonium oxalate extractable), respectively.^[5]

Shukla et al.^[6] prepared micronutrients-deficiency (Zn, Fe, Cu, Mn, and B) status maps based on the status of micronutrients availability in soils of the different districts of India. Map depicted Zn-deficiency status in soils of country (Fig. 1) revealed that out of 379 districts, 84 districts fall in the category where Zn deficiency is less than 10%, 53 districts fall in the range where Zn deficiency varied from 10% to 20%, 44 districts in 20–30%, 38 districts in 30–40%, and 40 districts in the category of 40–50% deficiency. Even after regular use of Zn fertilizer in many parts of the country, Zn deficiency in 120 districts more than 50%, indicating that about one-third of the country's vast area is acute deficient in Zn. The incidence of Zn deficiency was observed more in cereal belts of the country, particular rice and wheat growing areas, however, the distribution of Zn deficiency has changed and has extended to coarse cereals and pulse growing areas too. Increase in Zn-deficiency areas is due to intensification of agricultural systems inducing imbalance use of macronutrient, increasing Zn demand of new cultivars, altering Zn availability, and hastening depletion of readily-available soil Zn pools. Crops grown in these soils have low Zn content in shoot and seed.

A strong relationship between Fe availability in soil and occurrence of Fe anemia deficiency disorder is lacking in various parts of the country.^[6] By and large most of the soils do not respond to Cu and Mn fertilization. Deficiency of B is emerging fast in many soils due to extensive depletion of native soil B.

STATUS OF RESEARCH ON THE PROBLEM

In general, discussions on sustainable growth of agriculture revolve around food security. Conscientious deliberations

on the role of agriculture in human health remain a typical miss. Contrary to this prevailing apathy, agriculture is viewed as an instrument for public health. Since the use of pulses has been on the decline and intake of foods from animals is rather low, possible prevalence of micronutrient becomes common. In order to alleviate micronutrients and vitamin A malnutrition affecting over 3 billion people, a global challenging program on biofortification has been approved by the Consultative Group on International Agricultural Research. However, this single bullet solution does not seem wholesome to lessen micronutrient malnutrition when adversaries such as phytates, which reduces bioavailability continue to diminish value of ultra-nourishing crops. The high demand of marginalized sections of society and those who require more nutrients than others may not be entirely met by biofortified cereals alone. Hence, there is a need for innovating holistic-diet approaches combining high-yielding nutrient dense crops, inhibiting adverse effects of anti-nutrient factors, nutrient enhancing food enrichment techniques, and supplementation programmed to tackle hunger and malnutrition.^[5]

The physiological impacts of micronutrients are complex, relating to many bodily functions. Trails conducted in several countries indicate that duration and severity of major baby-killer such as diarrhea and pneumonia can be reduced by 30–50% by supplying adequate amount of vitamin A and Zn.^[7] In developing countries, Zn deficiency ranks 5th along with the Fe deficiency that is at 6th position globally, among the leading 10 risk factors.

In human nutrition, protein content of staple food grains has received maximum attention. Studies on other nutrients, such as beta-carotene, Fe, Zn, etc., have been initiated from 2002 to 2003 but that too in a non-inclusive fashion. Thus, whether it is unlocking the genetic diversity, improving bioavailability by promoting or demoting buildup, respectively of synergistic and antagonistic substances, enhancing bioavailability by modernizing indigenous cooking treatments or fortifying staple foods with nutrient-rich supplements and complements is in rudimentary and a highly fragmented condition. There is hardly any concerted effort to relate and quantify relationship within soil–crops–human health continuum. This sordid state of affairs prevails in India also when there is a strong database emanating from a 40-year program on micronutrient in soils and plants.

GLOBAL STATUS OF MINERAL NUTRITION DISORDERS AND THEIR EFFECT ON HUMAN HEALTH

Since the scientific and technical discoveries that food contains important vitamins and minerals and their deficiency may cause health problem, micronutrients became the focus of research for amelioration of their problems. The

Spatial Variation in Available Zinc Deficiency Status in Soils of Different Districts of India

Fig. 1 Spatial variation in available Zn-deficiency status in soils of different districts of India.

details of the disorders on account of mineral nutrition deficiencies and their likely impact on human health are listed as below:

Zn

Zn deficiency in human diet was reported as early as 1961 and its deficiency in human has been observed in Africa and Asia. It is estimated that >90% coverage with Zn supplementation program to prevent Zn deficiency would reduce child mortality by ~5% globally (WHO^[1] and Graham et al.^[8]). The WHO studies indicated that approximately 30% of children worldwide had stunted growth and thus suggesting wide spread occurrence of Zn deficiency. People feeding on grains and vegetation showed lower Zn content in their blood plasmas serum compared to areas that had high-available Zn status and lesser deficiency of Zn in soils.^[9]

Zn deficiency in children has been connected with allergic illness, eczema, learning problems, and hyperactivity. Zn deficiency also cause anorexia (failure to eat), growth retardation, skin lesions, rough and dry skin, immunosuppression, loss of taste, infertility, premature birth, and low birth weight. Zn supplements in diet reduced diarrhea in infants, improved intestinal permeability and appetite in children hence reduced significantly the health risk from Mn deficiency. The suggested safe recommended intake of Zn is 15 $\mu\text{g day}^{-1}$ but WHO^[1] recommended 45 $\mu\text{g Zn day}^{-1}$ as the upper limit and concentration of 150 $\mu\text{g day}^{-1}$ are toxic and cause impairment of health.

Fe

Fe deficiency in human largely results from its low Fe content in diet or its low dietary intake especially by poor individual in developing countries depending largely on cereal diet having low Fe content as well as low bioavailability. Prevalence of Fe deficiency anemia is reported wide spread in woman and children as a major micronutrient disorder problem in several parts of India. Severe Fe anemia was found in 34% in adolescent girls of Rajasthan and Gujarat state.^[10] Fe deficiency anemia is often associated with malaria and hookworm infections. The clinical syndromes in Fe deficient individuals are usually nervous, easily fatigued, lower weight gain, reduced appetite, palpitation on mild exercise, sore tongue, and angular stomatitis. Fe supplements in the form of capsule, tablets, and syrup with folic acid and vitamins are easily available in the market and are prescribed to the targeted Fe-deficient individuals and are helping in reducing the health risk from its disorders.

Cu

Cu is component of many enzymes that are involved in reducing molecular oxygen. Being an essential micronutrient

for man, it involved in lipid metabolism, bones development, and maturation of connective tissue. Signs of its deficiency in human are anemia (hypocupremic), neutropenia and leucopenia (lack of white blood cells), skeletal defects, degradation of nervous system, defective melanin synthesis that manifests as depigmentation or hypopigmentation (lack of color) of hair and skin, keratinization of hair, steely hair, cardiovascular disorders, osteoporosis, arthritis, infertility, and diarrhea. Cu depletion in man leads to elevated levels of serum cholesterol and reversed upon its supplementation. An intake of 2 mg Cu day^{-1} is adequate for healthy adults and 80 $\mu\text{g day}^{-1}$ for infants.^[8]

I

Deficiency of I is the world's most prevalent cause of brain damage. Goiter is the most common form of I deficiency disorder. Endemic goiter has been reported from all over Asia. Its deficiency causes cretinism in children born of parents residing in goiter endemic areas.^[7] The recommended dietary intake level is 150 $\mu\text{g capita}^{-1} \text{day}^{-1}$ or 1 mg or less in the thyroid gland.

Se

Se is a component of enzyme glutathione peroxidase, which protects against oxidative stress. The biological action of Se is similar to that of vitamin E and both substances are antioxidants in their own way and at its specific sites that protect the cells of the body against oxidative damage.

The most important disease that results from Se deficiency is "nutrient muscular dystrophy" termed as "white muscle disease." It manifests as chalky white striations and necrosis in skeletal and heart muscles. It causes hepatic necrosis, edema of colon, lungs, dystrophy of skeletal, poor reproductive performance, impaired immune responses, reduced milk, and egg production, etc., generally it causes death of swine. A daily Se intake below 20 mg caused "Keshan" disease—development of a cardiac disease, identified in 1935 in human and first Se disorder discovered in 1849 in the mountains and hills of Central China (WHO^[11]).

Vitamin A

Vitamin A deficiency (VAD) is a common cause of preventable blindness in children and a risk factor for increased severity of infectious disease and mortality. Its deficiency can lead to poor night vision, eye lesions and in severe cases, permanent blindness, increased illness, and death from infections. In pregnant women, VAD causes night blindness and may increase the risk of maternal mortality.

STRATEGIES FOR CORRECTION OF MICRONUTRIENTS MALNUTRITION IN HUMAN

Some of the interventions have been and could be used to alleviate micronutrient malnutrition problem in human globally are discussed below:

1. Supplementation

Micronutrient deficiencies have been successfully corrected through their supplements in the targeted population. Supplementation approaches are expensive short-term strategies as these rely largely on government or donor support and individual compliance. It is suitable for certain populations whose micronutrient status must be improved over a short period. Some of programs initiated by WHO for supplementation are salt iodization, vitamin A supplementation for children (6–59 months), etc.

2. Fortification

Fortification of food with micronutrients could be a cost-effective sustainable strategy for correcting their deficiencies to reduce health risks as the major cost of fortification and distribution is born largely by the consumers. At national level, fortification with multiple micronutrients could be a cost-effective method for correcting their deficiency disorders in risk groups or regions. Fortification strategy has been successful in many countries especially in the western countries where almost all the processed food are fortified.

3. Dietary modification

It involves changes in food selection patterns and/or in the traditional household methods for preparing and processing indigenous food so that foods with a high content and bioavailability of micronutrient throughout the year. Soaking has been advocated as a practical, non-enzymic, household method to reduce the phytic acid content of certain cereals maize and of legumes soybean, green gram, etc. Also flours produced from germinated and non-germinated staple foods can be mixed together and then soaked and fermented using microbial starter culture for 16–24 hours after which the flours are mixed with water to slurries and cooked to form porridges. This combination of approaches have been shown to reduce the phytic acid content by 90% as well as enhance Zn absorption, protein quality, protein digestibility, microbiological safety, and keeping quality besides decreasing toxins such as hemagglutinins and cyanide.

Improving Micronutrient Content in Seed

Biofortification through efficient crops/crop variety selection

Agriculture is a vital tool of ameliorating micronutrient malnutrition as it is a primary source of all the micronutrients consumed by human and animals worldwide. Approaches

include agronomic practices like cultivation of high density seed or varietal selection, advanced fertilization and organic matter practices, cropping system or farming planning soil, tillage and water management practices, and increased diversity by including of share of traditional millets, legume, or vegetable crops and cropping systems.

Narwal et al.^[12] revealed that the magnitude of susceptibility to Zn, Fe, and Mn deficiencies in different wheat varieties primarily depends on their capacity to utilize soil Zn, Fe, and Mn. However, there is an inevitable need to Zn, Fe, and Mn application on severely deficient soils regardless of wheat variety. While studying ferti-fortification of maize cultivars with Zn at different growth stages, Dhaliwal et al.^[13] found the increase in Zn concentration in all the five maize cultivars.

Microenriched fertilization/ferti-fortification of crops

Application of micronutrients through soil or foliar increased the micronutrients in seed and enhanced the yield. For certain essential micronutrient elements, e.g., Zn, Ni, I, and Se increasing soil available supplies to food crops can result in significant increases in their concentrations in edible plant products.

Micronutrients content in seeds and their bioavailability

Increased micronutrient concentration in seed does not qualify that it will be bioavailable to human and animals. Plant food can contain substances, i.e., antinutrients that interfere with the absorption or utilization of these nutrients in human. Bioavailable micronutrients in the edible parts of staple crops at concentrations high enough to impact on human health can be obtained through breeding, provided that sufficient genetic variation for a given trait exist, or through transgenic approaches. Studies in Thailand also suggest that additional Zn derived from rice grown on soils treated with Zn fertilizer could get absorbed and be potentially at a level that reduces the prevalence of Zn deficiency and has potential to improve growth and immune function in north eastern Thai school children (WHO^[11]).

Agronomic management for better nutrition

Agronomic practices besides genetic improvement play a vital role in increasing yield, high micronutrient density, and reducing antinutritional constituents in seed and fodders. Soil, foliar application, or seed treatment of micronutrient fertilizers are found quite efficient to enhance the micronutrient yield in micronutrient-deficient conditions and thereby improving cattle's and human nutritional health.^[5] Therefore, in order to enhance biofortification of micronutrients in plant parts and their translocation and accumulation in edible part, better understanding of mechanisms

that influences changes in rhizosphere, root cell sap pH, and production of siderophores is very much needed.

Management of Antinutrients

Absorption or utilization of micronutrients depends upon the substances like antinutrients present in food. Breeding of genotypes that contain lower concentrations of antinutrients or altering plant genes in ways that reduce or even eliminate antinutrient from plant foods is very much desired for enhancing Zn or Fe bioavailability. However, doing this involves risk, so it should be done with caution because many antinutrients are major plant metabolites may play important role in plant metabolism and growth and resistance to crop pest or pathogens. It is therefore, recommended that plant breeders closely scrutinize the strategy for increasing bioavailability of micronutrients for human food.

Zn bioavailability is markedly reduced because of high intake of phytate (inositol hexaphosphate) that adversely affects Zn absorption in the body. Phytate: Zn ratio of <5:1, 5–15:1, and >15:1 is considered as an index of high, moderate, and low bioavailability of Zn. Bioavailability of Fe depends upon quantity of heme- and non-heme-Fe diet and also balance between Fe absorption inhibitor and absorption promoter constituents (British Nutrition Foundation Task Force^[14]).

Mine Soils: Measuring Geogenic Carbon

David A.N. Ussiri

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Soil organic carbon (SOC) of the reclaimed minesoils (RMS) formed from coal mining often contains carbon (C) associated with coal particles from mining and the reclamation activities. This geogenic organic C (GOC, i.e. formed as a product of geological processes) derived from coal must be quantified in order to accurately quantify SOC pools, sequestration potential, and ecosystem C budgets of the RMS. The GOC contamination in RMS could lead to overestimation of recent organic C (ROC) pools derived from decomposition of plant biomass and sequestration rates and can also present major challenge due to large C background against which small changes in ROC must be measured. Standard procedures for quantifying SOC pools cannot distinguish GOC and ROC, and there is no standardized method for quantifying GOC in the environment. Methods for quantifying GOC in RMS have been grouped into microscopic, thermal, chemical, spectroscopic, isotopic, and combination of some of these methods. Radiocarbon analysis, one of the most reliable methods for quantifying GOC in RMS, needs specialized instrumentation, advanced computational skills, and high analytical costs, which preclude its adoption for routine soil analysis. Additional research and further evaluations of the existing techniques are needed to develop some reliable and cost-effective methods and ultimately propose standard GOC quantification methods that can be widely adopted for routine analysis.

INTRODUCTION

Minesoils are soils formed on landscapes altered by human activities of surface mining. Their original soil profile has been disturbed and sometimes partially or completely replaced by earth materials from the depths below 1 m, which are often less weathered than the original undisturbed soil. When these materials are exposed to surface or near surface environment, accelerated weathering may develop soils with properties that differ greatly from the original soil, depending on the parent material and the rate of weathering. Minesoils have developed as a result of disturbance and depositions through various anthropogenic activities such as coal mining, metal mining, sand and gravel mining, limestone quarrying, water bodies dredging, road building, construction, or other mining related activities. Sometimes referred to as spoils, anthropogenic soils or “Anthrosols,” these drastically disturbed soils exhibit profile characteristics, physical, chemical, and biological conditions that reflect anthropogenic perturbations rather than natural soil-forming processes. Most research dealing with development and properties of minesoils has focused on surface mining of coal, mainly due to extensive coal mining, which has resulted in disturbance of large expanse of land, and also the economic importance of

coal. Coal mining spoils include all non-coal materials disturbed by coal mining operations—rocks, rock fragments, soil, and other natural materials.

Surface mining operations reduce soil quality drastically by depleting soil organic carbon (SOC) as a result of enhanced mineralization, reduced litter input, soil erosion, and leaching. In addition to recent organic carbon (ROC) from plant litter, geogenic organic carbon [GOC, i.e., organic carbon (OC) that has been subjected to geological processes) may contribute to total OC of the minesoils formed from coal mining operations. The GOC collectively represents lithified plant debris at different degree of coalification formed by biological and geological processes over millions of years and contain a variable amount of aromatic structures depending on the degree of coalification. Decomposition of recent plant litter and other pedogenic processes lead to mixing of recently formed soil organic matter (SOM) with coal particles. Minesoils developed on calcareous parent materials such as siltstone, sandstone, and limestone may also contain significant quantities of soil inorganic C (SIC). Therefore, total carbon (TC) in minesoils developed from coal mining operations can be a mixture of: 1) SIC; 2) GOC; and 3) ROC. Due to the dark color of humus and its intimate mixing with fine coal particles, ROC and GOC cannot be distinguished by visual means. Characterization of ROC accrued as a result of

biochemical processes in reclaimed minesoils (RMS) is necessary for understanding soil development because the quantity and properties of recent organic matter (OM) from plant litter influence chemical and physical properties of soil. It is also important in C dynamics, ecosystem C budgets, and SOC sequestration rates in these soils. Standard methods commonly used for the determination of SOC such as dry combustion do not distinguish between ROC and GOC and may lead to overestimation of SOC pools and sequestration rates in RMS due to coal contamination. Available data suggest that fully restored minesoils have high potential for C sequestration compared to other terrestrial soils, especially during the first few decades following restoration. However, accurate quantification of SOC pools and C sequestration rates in these soils is a challenge, mainly due to coal contamination. Failure to correct for GOC contribution to SOC leads to overestimation of pools and rates of C sequestration in RMS. Available methods for the determination of GOC and correcting SOC pools for coal C and SIC are summarized in the next section.

ANALYTICAL METHODS FOR QUANTIFYING C OF DIFFERENT SOURCES IN RECLAIMED MINED LANDS

Inorganic C

In general, SIC occurs in neutral to alkaline RMS, predominantly as carbonate minerals—calcite (CaCO_3) and dolomite ($\text{CaMg}(\text{CO}_3)_2$). However, solid-phase carbonates in the form of nodules are also known to exist in some acid soil environments. Calcite is usually the dominant form in active pedogenic environments. As presence of SIC interferes with quantification of SOC, it must be removed prior to quantification of ROC and GOC. The SIC is usually removed by acid dissolution the following reactions (Eq. 1 and 2):

Addition of ferrous chloride or ferrous sulfate to the acid is recommended to minimize SOM decomposition during the acid treatment.^[1]

Geogenic and Recent SOC Separation and Quantification

Although some overlaps exist in the chemistry of recent SOM and coal, there are dissimilarities among the two OC sources, including chemical structures, functional groups composition, heat, and chemical reactivity resistance.^[2] For example, recent OM is dominantly composed of easily reactive and oxidizable organic compounds such as carbohydrates, protein, and lipids,^[3] while coal exhibits

highly aromatic and condensed structures as a result of partial decomposition and polymerization during the coalification process over a geological timescale. These differences have been exploited to develop different methods for distinguishing GOC from ROC and quantify the contribution of GOC to TC pool of RMS. Changes in structure during coalification are accompanied by a loss of easily mineralizable organic compounds while more recalcitrant moieties, mostly aromatic structures, are preserved. Although microbial decomposition of geogenic C in minesoils has been reported,^[4] coal is generally considered inert to chemical and microbial degradation^[3] due to the structural recalcitrance and inaccessibility of the small pores in the coal matrix to microorganisms. The quality and type of the ROC available for decomposition generally regulate microbial communities in RMS. Coal contamination contributes to irregular depth distribution of SOC in RMS (Table 1). Coal contamination also occurs in undisturbed soils adjacent to coal combustion plants, and soils ameliorated with coal combustion by-products such as coal ash.

The GOC quantification techniques in soil can be grouped into the following seven general categories: (1) optical and microscopic; (2) thermal; (3) chemical; (4) spectroscopic; (5) molecular markers; (6) isotopic; and (7) radiocarbon analysis. A summary of analytical methods for GOC quantification in RMS and sediments is presented in Table 2. These methods are based on the assumption that GOC and ROC can be distinguished on the basis of their optical, chemical, and/or spectroscopic properties. In practice, violation of these assumptions occurs to a varying degree depending on sample composition and method. Sometimes, to increase the confidence and accuracy of the results, combinations of methods are used. Some of these techniques are labor intensive and may require a level of instrumentation not readily available in many typical soil laboratories. The effectiveness of different methods in relation to coal rank, coal reactivity, and/or coal structure is presented in Fig. 1.

Radiocarbon Analysis Technique

Radiocarbon analysis is one of the most reliable methods for the quantitative measurement of GOC and closest to standard method. However, the specialized analytical equipment, which is not available in many laboratories, specialized skills, and high analytical costs preclude the adoption of this technique for routine analysis. The technique relies on distinguishing GOC and ROC based on the activity of radioactive C (^{14}C), which is unstable and decays over time based on the half-life of 5730 years. ^{14}C is present in environment in low quantities ($10^{-9}\%$), and coal, which formed millions of years ago, does not have ^{14}C activity (dead C)^[3] due to radioactive decay, while recent OM contains ^{14}C activity (active C) due to plant uptake of $^{14}\text{CO}_2$ from the atmosphere. After correction for the stable isotope and isotopic fractionation, plant biomass

has the same ^{14}C activity as the atmospheric CO_2 , incorporated into their tissue during photosynthesis, and ^{14}C concentration in living plant tissue is in equilibrium with $^{14}\text{CO}_2$ in the atmosphere. Once the tissue dies and metabolic function ceases, radioactive decay of tissue ^{14}C occurs. By measuring the ^{14}C concentration of the organic material and comparing the measured activity with that of standard modern C sample, the number of decay events per gram of C can be calculated based on the half-life of ^{14}C radioisotope.

The SOC in RMS consists of ROC with variable ^{14}C activity depending on the age of OM and GOC without ^{14}C activity. Based on difference in ^{14}C activity between the two C sources, the relative proportion of GOC can be calculated based on Eq. 3:

$$F = \left[1 - \frac{A_{\text{SOC}}}{A_{\text{recent OC}}} \right] \times 100 \quad (3)$$

where F is the fraction of GOC (%), A_{SOC} is the measured ^{14}C concentration of RMS, and $A_{\text{recent OC}}$ is the ^{14}C concentration of ROC derived from plant material. However, the relative ^{14}C activity in recent OM fraction is not well constrained due to variation in atmospheric $^{14}\text{CO}_2$ concentration as a result of atomic weapons testing from 1950. The ^{14}C concentration in plant tissues has systematically changed over time to reflect the atmospheric changes.^[9] This is also reflected in plant tissues. Rumpel et al.^[10] developed a modeling approach for estimating ^{14}C activity of recent OM in RMS by using time series approach. The ^{14}C activity of the RMS sample is determined using accelerator mass spectroscopy (AMS) after

removing carbonates by HCl treatment.^[11] In radiocarbon dating, year 1950 is year 0 before present (BP) by convention.^[12] The proportion of GOC and ROC can then be calculated using Eqs. 4 and 5:

$$\text{ROC}(\%) = \frac{A_{\text{SOC}}}{A_{\text{recent OC}}} \times \text{SOC} \quad (4)$$

$$\text{GOC}(\%) = 1 - \frac{A_{\text{SOC}}}{A_{\text{recent OC}}} \times \text{SOC} \quad (5)$$

where SOC is the organic C concentration of RMS.

Optical and Microscopic Technique

Optical and microscopic methods rely on optical properties of black color of coal materials to distinguish coal particles from other particles in soil. Optical method uses less sophisticated expertise of observation and microscope to draw the appropriate inferences. The morphology (particle size and shape), surface characteristics, and distribution of particles can also be determined using optical methods. Comparison with standard reference materials allows the identification and quantification of coal particles. Coal particles can be quantified *in situ* on petrographic thin sheets or polished sections. Coal particles can be concentrated by sieving and using sequential washing through a series of sieves of different mesh sizes or chemical pretreatments to improve the accuracy of microscopic analysis (Table 2). Chemical pretreatments include deflocculation of soil aggregates [generally with potassium hydroxide (KOH)] and removal of carbonates and silicates (with HCl and

Table 2 Summarized methods for determination of coal C in soils and sediments.

Method	Material analyzed	Pretreatment	Oxidation/treatment	Geogenic C determination	Merits	Limitations
Optical/Microscopy	Sediment	Sieving, deflocculating, removal of carbonates by HCl	None	Light microscope, electron microscope (SEM or TEM)	Simple Less expensive	Can only detect larger particles Cannot detect coal degradation products qualitative
Thermal oxidation	Soil	Sieving (<2 mm) Removal of carbonates and silicates with 1 M HCl, and 10% HF, respectively	Thermal, heated at 375°C for 24 hr	C, N elemental analysis or mass balance	Less expensive Adaptive for routine analysis	Oxidation temperature overlap for recalcitrant OM and coal Not suitable for lower rank coal
Thermal oxidation and acid hydrolysis	Soils	As above	6 M TFA at 100°C for 18 hr, 6 M HCl 110°C 24 hr, thermal oxidation at 375°C for 24 hr	C, N elemental analysis of the residual		
Chemical oxidation method	Sediments	HCl, HF	Hydrogen peroxide	Counting	Less expensive Adaptive for routine analysis	Labor intensive Chemical oxidation overlap between recalcitrant OM and lower rank coal Overestimation of coal contamination due to oxidation overlap Not suitable for lower rank coal
	Sediments	HCl, HF	$\text{Cr}_2\text{O}_7^{2-}$, H_2SO_4 , heated at 50–60°C for 60 hr	Counting, mass loss		
	Coal	HCl, HF	H_2O_2 , KOH	Infra-red spectroscopy		
	Sediments	HCl, HF	$\text{Cr}_2\text{O}_7^{2-}$, H_2SO_4 , heated to 60°C, 72 hr + KOH, H_2O_2 , heated to 60°C 8 hr	Elemental C, N, H analyzer		
	Sediments	HCl, HF	Hot nitric acid (HNO_3)	GC, combustion, MS		
	Soils	none	$\text{Na}_2\text{S}_2\text{O}_8$ with NaHCO_3 buffer	Elemental analyzer		
	Soils	none	NaOCl + acetic acid + DI water	Elemental analysis, ^{13}C NMR spectroscopy		
Chemical extraction, chemical oxidation, thermal oxidation	Soils	HCl, HF	0.5 M NaOH extraction, 65% HNO_3 , 1% HCl, thermal treatment, 340°C in oxygen or air	Elemental analysis, mass balance	Improved coal recovery	Labor intensive
	Soils

HF, respectively) followed by microscopic observation under oil suspension on glass slides. Brightfield light microscope, scanning electron microscope (SEM),^[5] or transmission electron microscope (TEM) can be used depending on the particle size. Coal particles are distinguished from other mineral particles based on shape and color and quantified based on distribution area.^[5] Coupling SEM with energy dispersive X-ray spectroscopy allows the determination of the chemical composition of the particles and their O–C ratios at a nanometer resolution.^[14] If the SEM is coupled with an elemental analyzer, coal particles can be identified and the amount present can be quantified based on composition (C, H, and N) and element ratios.^[15] This procedure is time-consuming and its accuracy relies on correct differentiation between coal and other dark-colored (opaque) debris in the soils. Microscopic technique can only detect relatively larger particles and cannot detect coal degradation products.

Thermal Oxidation Techniques

Thermal oxidation methods utilize the difference in heat resistance between recent SOM and coal particles under specific heating conditions (temperature and oxygen). Heating conditions are selected such that ROC is oxidized and GOC remains unaffected after sample treatment. By adjusting the combustion temperature and duration, ROC

can be oxidized and the remaining GOC can subsequently be quantified using elemental C analysis or C mass balance (Table 2). The efficiency of the thermal oxidation method varies with coal rank. If the RMS contain low-rank brown coal particles, the thermal oxidation method is not suitable, because some of the coal particles will be oxidized along with recent OM fractions, leading to underestimation of geogenic C concentration.

An example of thermal analysis technique that allows for the determination of physical properties of OM being oxidized (mass, temperature, and enthalpy), as the sample is subjected to a controlled temperature program.^[16,17] It involves heating a sample incrementally in a temperature controlled thermogravimetric analyzer, where changes in mass, temperature, and enthalpy of the sample are recorded during the oxidation process.^[16] Weight losses at temperatures >200, 250, and 395, 400–520, and above 600°C are generally attributed to loss of various forms of moisture, SOM oxidation, coal oxidation, and decomposition of carbonate minerals, respectively.^[16] Other variations of thermal oxidation approach are summarized in Table 2.

Thermal oxidation methods are based on the assumption that temperature conditions can be selected to thermally oxidize ROC fractions while GOC remains unoxidized. However, due to close associations and incorporation of coal particles within the macromolecular structure of SOM,

selective oxidation of recent SOM without oxidizing coal, especially those of lower rank remains a methodological challenge. Both recent SOM and coal comprise a continuum of OM compounds that overlap in their thermal resistance and chemistry.^[18] Less refractory C compounds of coal are oxidized along with ROC while highly refractory ROC remains unoxidized at the selected temperature. This overlap proves to be problematic, if low rank coal particles such as lignite are the sources of coal particles present in RMS. There is no single, universally accepted temperature limit for separating OM from the coal of different ranks. As a result, operationally defined temperature cutoffs are set empirically and probably will vary with the rank of coal particles present in RMS (Fig. 1).

Chemical Methods

Similar to thermal oxidation, these techniques rely on resistance of coal to chemical oxidizing agents for quantifying GOC in soils and sediments. For effective oxidation, soil or sediment samples must be deflocculated to expose occluded OM and also pretreated to remove carbonates and silicates prior to chemical treatment. The presence of carbonates and silicates interferes with the chemical oxidants and reduces the efficiency of SOM removal. In calcareous soils, e.g. carbonate coatings favor occlusion and thus physical protection of OM against chemical reaction. Carbonates are removed by dilute acid reaction, while hydrofluoric acid (HF; usually $\leq 10\%$ by volume) is commonly used for demineralization prior to chemical treatment (Table 2). The ROC, comprising humified SOM, is removed by chemical oxidants such as sodium hypochlorite (NaOCl), hydrogen peroxide (H_2O_2), potassium dichromate ($K_2Cr_2O_4$), sulfuric acid (H_2SO_4), nitric acid (HNO_3), disodium peroxodisulfate ($Na_2S_2O_8$), permanganate ($KMnO_4$), or ultraviolet light. Mild alkaline solutions (i.e., <0.5 M NaOH) have also been used to extract recalcitrant ROC.^[8] The efficiency of recent SOM removal from soils by chemical reagents is determined by reaction conditions (temperature, time of contact, and addition of catalysts) and RMS properties (soil pH, mineralogy, SOC concentration, and quality). Some of the chemical reagents are often used in combination and at selected elevated temperatures to increase the efficiency of recent OM removal. The remaining resistant OC fraction can be characterized using different methods, including elemental, microscopic, and spectroscopic methods.

Accurate quantification of GOC concentration in soils requires complete oxidation of recent SOM without removing GOC. Reaction with coal can cause underestimation, and incomplete removal of SOM could lead to overestimation of GOC concentration in RMS. Due to incomplete oxidation of recent OM, spectroscopic techniques such as ^{13}C nuclear magnetic resonance (NMR) analysis have the potential of distinguishing GOC and recalcitrant ROC, based on differences in functional

groups, and are used for quantifying the recalcitrant ROC resistant to oxidizing agents.

Both ROC and GOC consist of a continuum of organic material ranging in chemical oxidation resistance. Resistance of coal to chemical treatment is rank dependent, such that coals of lower rank (e.g., brown coal) are less resistant to chemical oxidation and may be oxidized along with recent OM. Similarly, highly recalcitrant recent OM is also resistant to chemical oxidants. Therefore, in RMS contaminated with low-rank coal particles, chemical methods could underestimate GOC. In addition, recalcitrant recent OM may remain after the chemical treatment and that could lead to the overestimation of GOC.

Ussiri and Lal^[8] developed chemi-thermo method, which combines chemical extraction, chemical oxidation, and heat oxidation at a controlled temperature for removing ROC and quantifying GOC using elemental C analyzer. It involves subjecting a soil sample to a series of chemical treatments and heat oxidation, to remove various fractions of ROC; then the remaining GOC is quantified by elemental C analysis.^[8]

Molecular Biomarkers

In the molecular approach, functional groups and/or classes of organic compounds associated with coal are first identified and, based on the concentration of these chemical markers, the coal content of the samples is determined.^[14,19] Oxidative degradation of coal produces benzenepolycarboxylic acids (BPCA), resulting from conversion of polycyclic C or substituted aromatic C. The oxidative degradation of coal can be achieved through the use of concentrated acid digestion. GOC is estimated based on reference standards by quantifying BPCA using gas chromatography.^[19]

Spectroscopic Techniques

Spectroscopic methods use a spectroscopic analysis to quantify GOC based on relative abundance of specific functional groups characteristic to coal, as revealed by spectral analysis, generally after oxidative removal of non-coal SOM by a chemical pretreatment.^[2,20] Two methods commonly applicable to GOC determination are infrared (IR) and NMR spectroscopies. The IR spectroscopy is based on the specific response of organic groups to IR light in different regions of the IR spectrum, and NMR spectroscopy identifies spectra regions characteristic of functional groups in coal and estimates coal concentration in the RMS samples based on the relative strength of the identified bands. Fourier transformed IR spectroscopy and diffuse reflectance Fourier transform IR spectroscopy analyses are commonly used to examine complex organic substances in the solid state. Interpretation of spectra information and quantification of different OC sources is achieved through

Multivariate data analysis and predictive modeling using partial least squares.^[2]

Solid state ^{13}C CPMAS NMR technique determines structural information of SOM based on distribution of ^{13}C content of functional groups and infers the relative contribution of different C sources in the sample based on relative functional groups distribution. The peak intensity of NMR spectroscopy is approximately proportional to the fraction of C represented by the structural fingerprint assigned to the abscissa of the spectrum (chemical shift). The structural composition of coal differs considerably from that of recent SOM, and their functional group differences can be utilized to quantify the contribution of GOC in RMS. However, for mixtures of macromolecules such as those encountered in RMS, the NMR spectra becomes a complex assemblage of overlapping peaks where only the average structural entities can be discerned.^[3] The distinct dominance of aliphatic (alkyl C) and aromatic C in brown coal was used as a fingerprint for brown coal presence in RMS and the signal intensity ratio (A) as an indicator of the presence of lignite in soils, where A is computed as

$$A = \frac{(\text{alkyl C} + \text{aromatic C})}{(\text{O} - \text{alkyl C} + \text{carboxylic C})} \quad (6)$$

The value of A is typically between 0.8 and 1.2 for non-contaminated soils and between 1.6 and 2.2 for soils contaminated with brown coal.^[20] Thus, the value of A increases as lignite contribution increases.

^{13}C Stable Isotope Approach

The ^{13}C isotope technique is also a potential tool for estimating GOC and ROC contribution in RMS. The GOC is normally enriched in ^{13}C compared to recent OM probably due to selective preservation of OM during coalification and microbial discrimination against the heavier isotope. Microbial discrimination against ^{13}C leads to relative enrichment of ^{13}C in plant materials resistant to microbial mineralization.^[21] Plant remains underwent extensive transformation and decomposition prior to geological coalification process,^[22] resulting in relatively narrow range of $\delta^{13}\text{C}$ stable isotope composition of coal (-22‰ and -27‰) compared to that of C_3 recent OM (-22‰ to -35‰).^[23] The $\delta^{13}\text{C}$ stable isotope ranges are very stable and does not change significantly with rank or maturity of coal.^[22] A simple two-compartment model can be used to estimate the proportions of coal C and ROC in RMS. However, this approach has not been used for quantifying GOC in RMS where recent OM can be dominantly C_3 or C_4 plant sources.

CONCLUSION

Minesoils formed from coal mining can play a significant role in C sequestration climate change mitigation. However, accurate potential of these soils can only be estimated

if GOC contamination can be quantified and adjusting OC pools for coal contamination. To obtain accurate estimations of SOC pool and sequestration rates, cost effective, reliable, and standardized methods are needed for routine quantification of the relative contribution of coal C to SOC in RMS. Compared to recent OM, coal is highly aromatic and hydrophobic in nature, a characteristic that make coal-derived OC relatively inert to various chemical oxidants and highly resistant to thermal at lower temperatures, depending on coal rank. The differences in chemical and thermal oxidation properties and also functional group composition among coal and recent OM form the basis for the various techniques for estimating GOC and ROC in RMS. The major limitation of thermal and chemical oxidation methods is their inability to remove highly recalcitrant ROC and also oxidation of lower rank coals together with ROC. The ^{13}C NMR spectroscopy method generally differentiates between ROC and GOC based on relative abundance of specific functional groups characteristic of coal or recent SOM. While structural and compositional differences between GOC and ROC are fairly well understood, overlaps exist in the spectral signature of these C sources, which makes it a challenge to quantitatively estimate GOC using spectroscopic methods. Radiocarbon analysis is one of the most reliable methods for quantitative measurement of GOC in RMS and closest to reference method, but high analytical costs, requirement of specialized analytical instrument, as well as, specialized expertise preclude its adoption for routine soil analytical laboratory. Although various methods have been employed in quantifying GOC in RMS, there are no standard methods for that purpose. Thermal and chemical methods have several shortcomings including incomplete oxidation of ROC and variable efficiency of the methods depending on reaction conditions and rank of the coal particles in RMS. Nonetheless, with further research, they offer a great potential for methods that could be widely adopted for GOC determination in RMS. Systematic inter-laboratory comparison of analysis of well-defined standard materials could be a crucial step toward that goal.

Abstract

In the United States, surface mining has created over 1.82 Mha of degraded land, mostly in the Appalachian region. With demand for bioenergy derived from renewable biomass resources increasing and a finite availability of land and water resources, interest for bioenergy crop production with low input demands on marginal lands (i.e., miscanthus) is subsequently increasing. However, physical (available water content, high compaction), chemical (pH, lack of nutrients, plant toxicities), and biological (low organic carbon content) soil properties have to be appropriately amended for miscanthus to have a large impact as a biomass energy crop in minesoils in the Appalachian region.

INTRODUCTION

Termed as a second-generation biofuel crop, the use of miscanthus (*Miscanthus giganteus*) is a positive step toward a more sustainable bioenergy resource compared to first-generation biofuels that are derived from plant sugars, starches, and oils. This is in large part due to miscanthus having a perennial life cycle, low maintenance and nutrient requirements, and high biomass yield potential.^[1] Consequently, the establishment of miscanthus compared to annual crops such as maize (*Zea mays* L.) over the long term can typically improve soil nutrient recycling, soil carbon (C) sequestration, and controlling soil erosion, especially in degraded lands.^[2,3]

However, there are concerns about bioenergy crops competing for finite land and water resources with annual grain crop production in the United States.^[4] One approach to addressing these concerns is to reserve land that is rich in soil fertility with no environmental restrictions for food and feed production, while marginal lands are primarily used for establishment of bioenergy crops that have low input demands and are tolerable to environmental stresses. This entry provides an overview of the extent and types of minesoils and the constraints and limitations for miscanthus production on those marginal lands.

DEFINING MINESOILS

Extent of Degraded Land

Surface mining for coal and other minerals has created ~1.82 Mha of degraded land across the United States, of which only 65,000 ha (4%) is reclaimed and bond released (Fig. 1).^[5] Much of these degraded lands have gone

through reclamation practices that reestablish native vegetation or grass and legume mixtures, which promote soil formation and stabilization during the first 5 years in humid and subhumid regions in the United States. These soils are termed minesoils, because they are human-made and differ from other disturbed surface mined soils that were abandoned and little to no attempt of reclamation and revegetation was made.^[6] There have been at least 34 minesoils that have been identified as individual soil series, mostly in the Appalachian region in land mined for coal.^[6]

Reclamation of Mined Land

Surface mining for minerals and metals results in the destruction of the existing vegetation and soil profile, as well as severe disruption of soil microbe populations and nutrient cycling. In 1977, the U.S. government enacted the Surface Mining Control and Reclamation Act (SMCRA), which requires grading, of the top soil replacement, and reestablishment of vegetation of the disturbed land to conditions prior to mining.^[7] These regulations were relaxed to establishing landscape conditions and vegetation, which minimized soil erosion, acid mine drainage, and pollution of natural waters.

During surface mining, the vegetation and top soil are first scalped and stockpiled for later use. Then, explosives are used to remove the overburden material (subsoil and rock fragments) from the attended extraction material (typically coal in the Appalachian region), creating a mix of spoil. Once the attended minerals or metals have been extracted, the pit that has been formed is backfilled with the spoil. Grading of spoil is done to decrease the steepness of slopes and reduce soil surface runoff and slippage of spoil piles. However, the heavy equipment used during the

Fig. 1 Amount of reclaimed mine land in the United States.
Source: From Office of Surface Mining.^[5]

grading causes a high level of compaction. Finally, the original stockpiled soil is replaced back onto the surface where appropriate soil amendments and seeding mixtures are applied for revegetation.

Given that minesoiils are human-made, landform decisions can be made based on post-mining land uses that would be more valuable for agriculture or forestry. In the Appalachian region, hilly terrain is common, and although surface mine reclamation generally requires that lands be restored to the approximate original contour, it would be advantageous to construct land that is flat for row crop production.^[8] Ideal grading of minesoiils for row crop production should have a 2–3% gently sloping surface in humid regions to avoid depression areas that cause water logging, while still minimizing soil erosion.^[8] Minesoiils with slopes greater than 15% are typically not suitable for miscanthus production, as full canopy establishment takes over 2 years, leaving the soil surface vulnerable to erosion without some form of cover vegetation.

Top soil replacement with greater silt and clay contents and higher nutrient capacity, biological activity, and water retention than overburden spoil is a critical step in providing a suitable growth media for revegetation. The 1977 SMCRA required that at least 15–20 cm of the top soil

Fig. 2 Soil profiles starting from non-disturbed to development of new soil horizons in minesoil over time.

be removed prior to mining, stockpiled under appropriate conditions (aerobic conditions), and replaced back on the surface. However, in sloping regions such as the Appalachian, the top soil is often too shallow, rocky, infertile, and too acidic to use for revegetation. Under these circumstances, a substitute material such as overburden material mixed with sewage sludges, residue mulch, manure, sawdust, wood chips, and papermill sludges can be used in the place of original top soil.^[9]

General Properties of Minesoiils

Minesoiils are pedogenically young soils developing from replacement of top soil and mine spoil, typically expressing weak soil structure that contributes to high compaction and poor hydraulic conductivity (Fig. 2). Minesoiils generally have an A–C or A–AC–C horizon soil profile, the formation of a shallow A horizon often takes as little as a year, characterized by spoil loosening and aggregation formation.^[6] After 5 years, A horizons have been reported to range from 5 to 20 cm deep in the Appalachian region (Table 1), with weak granular or subangular blocky structure and enriched with organic matter.^[6]

Table 1 Range and mean of soil physical characteristics of minesoiils in the Appalachian region.

Variable	Range	Mean
Coarse fragments >2 mm (%)	4–71.5	26.5
Clay (%)	13–51.7	31.7
Bulk density (g cm ⁻³)	1.32–1.70	1.53
Cone penetrometer resistance (MPa)	0.9–3.7	1.9
Available water capacity (cm ³ cm ⁻³)	3–33	13.5
A horizon depth (cm)	5–20	12.6

CONSTRAINTS AND LIMITATIONS OF ESTABLISHING MISCANTHUS IN MINE SOILS

Miscanthus Production in Minesoils

There is only sparse, readily available published data on bioenergy crop production in marginal lands, especially in minesoils, which is the focus of this entry. During the first 2 years of miscanthus establishment in Ohio, biomass yields ranged from 0.1 to 4 Mg ha⁻¹,^[10] although harvesting is not recommended until at least the 3rd year. This would allow for sufficient time of the rhizomes to increase their nutrient reserves and increase tiller production, so as not to reduce population stands. Once fully established, miscanthus yields ranged from 2 to 18.7 Mg ha⁻¹ in Ohio and West Virginia, varying due to stand establishment, which is significantly affected by physical and chemical properties of minesoils and environmental stresses such as flooding and drought.^[10,11]

Physical Soil Properties

Minesoils in the Appalachian region typically have low water-holding capacity and high soil compaction due to their inherently high coarse texture and rock fragments content ranging from 4% to 72% (mean 26%; Table 1) and are the primary constraints for bioenergy crop production.^[12] Minesoils with greater than 40% coarse fragments (>2 mm), which in general are those with no or little top soil with silt and clay applied, have a water-holding capacity ranging from 3% to 15% resulting in limiting plant growth.^[13] Additionally, in regions that receive less than 70 cm of rainfall, yields could fall lower than maize and switchgrass (*Panicum virgatum*), due to miscanthus having a larger water uptake requirements.^[11,14]

Fig. 3 Soil compaction effect on miscanthus growth in a mine-soil near Zanesville, Ohio.

Severe soil compaction also reduces water-holding capacity and pore space, restricting root growth in drought conditions, especially in minesoils with less than 60 cm of effective rooting depth (Fig. 3).^[12] For many plants, a soil bulk density greater than 1.7 g cm⁻³ or cone penetrometer resistance greater than 2 MPa in minesoils (Table 1) is very restrictive for root growth. Additionally, in excessive wet settings, soil compaction can also cause perched water tables resulting in anaerobic conditions for root growth. Furthermore, overwintering survival during the first year of establishment largely depends on soil and rhizome moisture content.^[15] In Ohio, overwinter survival rates of miscanthus in minesoils ranged from 40% to 70% in non-compacted soil.^[10] However, in the same study, soils that were water logged due to compaction had overwinter survival rates only from 20% to 55%.

Chemical Soil Properties

Chemical soil properties of minesoils important to growth of miscanthus include pH, concentration of soluble salts, nutrient availability, organic (C), and metal toxicity. In the Appalachian region, pH in minesoils ranged from 6.5 to 7.8 in calcareous soils and 4 to 6.2 in non-calcareous spoils.^[12] The ideal soil pH range for most plants is 6.0 to 7.5, although miscanthus can tolerate soils with pH ranging from 4.9 to 7.6.^[12] Potential uptake of toxic levels of metals such as copper, lead, nickel, zinc, and aluminum is primarily only a concern in acidic soils. Other potential toxicities from additions of industrial wastes and soil amendments include mercury, arsenic, cadmium, and selenium.^[16]

Nutrient cycling, specifically nitrogen (N), phosphorus (P), potassium (K), calcium (Ca), and soil organic carbon (SOC), is severely disrupted during mining, due to declines in soil microbial activity and recycling of nutrients between plants and microbes. In minesoils, soil fertility varies from low to ideal conditions in well-established minesoils, although young minesoils frequently have very low nutrient concentrations in the soil.^[12] The SOC concentrations in minesoils in the Appalachian region range from 5 to 44 g kg⁻¹ (mean 15 g kg⁻¹). Total soil N concentrations in minesoils in the Appalachian region range from 0.4 to 1.9 g kg⁻¹ (mean of 1.2 g kg⁻¹), within range of what is considered adequate for crop growth (1–1.5 g kg⁻¹). However, N uptake demand is much higher in miscanthus compared to annual row crops after the 3rd year of establishment, and N fertilization may be needed to maintain or increase productivity in minesoils. Total soil P concentrations in minesoils in the Appalachian region range from 27 to 129 mg kg⁻¹ (mean of 56 mg kg⁻¹), well below adequate soil levels for crop growth at 100–150 mg kg⁻¹. This is of particular concern as miscanthus nutrient requirements for P (2–5 kg Mg⁻¹ of dry matter), K (0.8–1.2 kg Mg⁻¹ of dry matter), and Ca (0.3–1.1 kg Mg⁻¹ of dry matter) are high.^[17] Although miscanthus has low demand for inputs due to its nutrient cycling between rhizome and

aboveground biomass, attention must be given to how much nutrients are removed when harvesting biomass and, subsequently, how much nutrients are needed to be added back to maintain long-term productivity.^[12] This is especially true in minesoils, where these soils typically do not have high nutrient reserves, due to limitations in nutrient capacity from high content of coarse fragments and low organic matter in some cases.^[12]

CONCLUSION

Minesoils that are under cool season forage grasses may be underutilized when future economic potential of bioenergy crop production such as *miscanthus* is considered. Once physical (available water content, high compaction), chemical (pH, lack of nutrients, plant toxicities), and biological (low SOC) soil properties have been appropriately amended, *miscanthus* has a large potential as biomass energy crop in minesoils in the Appalachian region. However, there have been few field studies that have examined fertilization requirements for bioenergy crop production in minesoils to determine optimum rates while minimizing negative environmental impacts. Further research is needed before *miscanthus* can be implemented at a commercial scale in minesoils.

Mine Soils: Open Cut Mine Rehabilitation

Douglas J. Dollhopf

Department of Land Resources and Environmental Sciences, Montana State University, Bozeman, Montana, U.S.A.

Abstract

Land rehabilitation sciences at open pit mines has developed at an exponential rate. Grading the mined landscape to the approximate original contour, use of adequate amounts of—and quality of—coversoil and development of *in situ* soil treatments at sites where coversoil resources were absent have all provided means to establish a diverse plant community.

INTRODUCTION

Mining directly disturbs approximately 240,000 km² of the earth's surface.^[1] Surface mining methods may be classified as: 1) open pit mining; 2) strip mining; 3) dredging; and 4) hydraulic mining.^[2] Open pit mining includes quarries used to produce limestone, sandstone, marble, and granite; pits used to produce sand, gravel, and bentonite; and large excavations used to produce talc, copper, gold, iron, silver, and other metals. This mining method is distinguished by having one large pit or numerous small pits across the landscape. State or federal governments establish regulations that require the operator to restore the land to an approved land use(s) that is equal to or better than the premine land use. The approved postmine land use(s) is instrumental in determining the final graded topography and vegetation community.

LANDSCAPE REGRADING

Reclamation of an open pit mine must address the open pit itself, waste rock removed from the pit to gain access to the ore, tailing impoundments, and access roads (Fig. 1). For open pit mines, complete backfilling of the pit is not usually economically feasible. Because the pit remaining after mineral extraction may be hundreds of feet deep, the cost of moving waste rock back into the depression is prohibitive. Surface and groundwater may flow into the depression after mining is terminated and an impoundment develops. Pit slopes should be reduced to the limits required for safe access for humans, livestock, and wildlife. Pit slopes should not be permitted at gradients that jeopardize the success of postmine reclamation.

COVERSOIL RESOURCES

Successful plant community establishment on an open pit mine site is a direct function of the coversoil quality

applied. Coversoil suitability criteria vary in the United States from state to state but are similar to those presented in Table 1. The coversoil resource emanates from two procedures: 1) salvaging the natural soil resource from the area to be disturbed; and 2) mining unconsolidated geologic stratum when the soil resource is absent. Under U.S. federal and state mine regulatory programs, all portions of the soil resource shall be salvaged in a project area if it meets physicochemical suitability criteria. Soil materials that do not meet these suitability criteria are generally not used because they may impair plant establishment and growth. Once the soil resource is salvaged, it should be directly hauled to an area that has been backfilled and is ready to receive coversoil. Direct hauled soil contains a viable seed bank, mycorrhizal associations, organic matter, and nutrients that aid in plant establishment. Conversely, if the soil resource is stockpiled, these resources will deteriorate with time.

Prior to implementation of mine land reclamation regulations during the 1970s and 1980s, open pit U.S. mine operations often did not institute land reclamation. The soil resource was not salvaged, the disturbed landscape was not graded to the approximate original contour, and the site was not seeded. Consequently, the soil resource was lost. These lands are being coversoiled using unconsolidated geologic stratum. Valley fill areas adjacent to the disturbed landscape often contain alluvial materials beneath the soil resource that meet all soil suitability criteria (Table 1), except organic matter is absent. This alluvial stratigraphy may be 10–30 m thick or more. Earth moving equipment is used to stockpile the soil resource, separating true topsoil (A horizon) from subsoil (B and C horizons), to enable excavation of deeper alluvial material. Following placement of this alluvial coversoil on the disturbed landscape, the pit created is contoured and the stockpiled soil resource is replaced. Lands receiving coversoil emanating from a geologic stratum should have organic matter applied to

Fig. 1 Large open pit mine in the United States with water impounded in bottom.

expedite establishment of nutrient cycles in the plant root zone. Cattle manure and municipal compost are two sources of organic matter used in land reclamation projects.

COVERSOIL THICKNESS REQUIREMENTS

The thickness of coversoil required for maximum vegetation performance is dependent on several factors including the 1) vegetation species present; 2) local climate; 3) coversoil quality; and 4) physicochemical quality of the substrate beneath the coversoil. The maximum rooting depth of many rangeland ecosystem plant species is less than 45 cm and generally does not exceed 100 cm.^[3] Investigators found that a minimum of 40 cm to a maximum of 150 cm of coversoil is needed for optimum plant growth.^[4–8] This wide variation of findings is a function of site specific conditions identified before. The Barth^[4] investigation is representative of most research. This investigator found that generic spoil, defined as non-alkaline and non-saline loams with sodium adsorption ratio (SAR) below seven,

Table 1 Coversoil suitability criteria.

Soil parameter	Suitability criteria
pH	>6.5 and <8.0 standard units
Electrical conductivity	<4.0 dS/cm
Exchangeable sodium percentage	<12%
USDA textural classes (12 types)	All suitable except clay, loamy sand, sand
Rock content (particles >2 mm diameter)	
Slope gradients <25%	<35%, weight basis
Slope gradients >25%	>35% and <60%, weight basis
As, Cd, Cu, Pb, Zn, other metals	Near back ground levels, i.e., no enrichment
Organic matter	>0.5%, weight basis

showed an increase in plant production up to a coversoil depth of approximately 50 cm. Sodic spoil, or material with SAR of 26 or higher, required a minimum of 70 cm of coversoil to reach maximum cool season grass production. Coversoiled acid spoils, defined as spoils exhibiting pH values between 3.6 and 4.3, revealed increased grass production up to the maximum coversoil depth used in this study (152 cm).

IN SITU SOIL RECLAMATION

In situ soil reclamation at open cut mine sites means no coversoil resource is used. Chemical and/or organic amendments are applied to the graded spoil, tailings, or waste rock landscape to enable plant establishment and growth.

In situ Sodic Minesoil Remediation

Thousands of hectares of land in Wyoming and Montana were open pit mined for the mineral bentonite prior to passage of state regulations requiring land reclamation. The absence of a soil resource to reclaim these lands means the plant ecosystem must be established on graded spoils. Spoils are overburden materials cast aside to access the underlying mineral, bentonite. These overburden materials have a sodic condition [exchangeable sodium percentage (ESP) 20–40], clay texture (60% clay) dominated by swelling clay minerals such as smectite, and preclude plant establishment and growth. *In situ* soil remediation requires a twofold approach: 1) permanently reduce ESP to less than 10 within the 0–30 cm soil profile and 2) provide an organic amendment to immediately prevent soil crust development and increase water infiltration. Crust development in these clayey-sodic soil systems is precluded with applications of wood chips from saw mill waste or manure.^[9] Applications of gypsum, calcium chloride, magnesium chloride, and sulfuric acid to these sodic soils have been shown to be effective at reducing the ESP to acceptable levels in minesoils and provide a root zone suitable for plant growth.^[10]

In situ Acid Minesoil Remediation

Open pit mines associated with gold, silver, and metal extraction from sulfide ore bodies frequently produce tailings impoundments and waste rock areas that are acidic (pH 2.5–5.5) and fail to support plant growth. Soil acidity is formed when sulfide minerals, such as pyrite, are exposed to oxidizing conditions in the presence of water. In the absence of a coversoil resource, tailings and waste rock material are treated with alkaline amendments to permanently neutralize the soil acidity. Soil analysis of the acid base account and active acidity enables

determination of the calcium carbonate requirement.^[11] Amendments used include calcium carbonate, calcium hydroxide, and calcium oxide. *In situ* treatment with amendments should be at least to the 45 cm soil depth and special engineered plowing equipment is required to attain this depth of incorporation.^[12]

ACID MINE DRAINAGE

Upon exposure of open pit mine wastes to water and oxygen, sulfide minerals oxidize to form acidic, sulfate rich drainage.^[13] Iron-oxidizing bacteria, e.g., *Thiobacillus ferrooxidans*, expedite the acid producing reaction rate up to a million times. Metal composition (aluminum, copper, iron, manganese, lead, zinc, and others) and concentrations in acid mine drainage (AMD) depend on the type and quantity of sulfide minerals present. Approaches to prevent or treat AMD include: 1) removal of air and water from the sulfide body that is disturbed; 2) wetland construction to precipitate contaminants with oxidation ponds and anaerobic-microbial reactions in plant root zones; 3) underground anoxic- and aboveground open-limestone drains to raise water pH; and 4) treatment of drainage with neutralizing chemicals such as hydrated lime, quicklime, soda ash, caustic soda, and ammonia.^[14]

STEEP SLOPE RECLAMATION

Open pit mines are frequently located in mountainous terrain and reconstructed slopes may have gradients as steep as 50%. Sediment yields tend to increase linearly with slope gradient. There is an inverse relationship between soil loss on slopes and rock cover.^[15] High rock content in soils increases infiltration rate and surface roughness decreasing runoff and soil loss. As erosion occurs on rocky soil, rock cover increases as the coarse fragments below the surface are exposed. This armoring of the soil surface can help reduce soil erosion. It has been reported that plant growth may be impaired when soil rock content exceeds 35%.^[16] High rock contents of 35–60% applied on steep slopes (Table 1) may impair plant growth but are considered a best management practice to facilitate plant establishment and slope stability.

Construction of shallow pits across steep slopes is commonly practiced to increase water storage on the slope and minimize runoff. Pitting techniques using equipment referred to as Dammer-Diker, gouger, and dozer basin blade have been shown to be effective in controlling sediment loss.^[17]

CONCLUSION

Since the 1970s, land rehabilitation sciences at open pit mines developed at an exponential rate. Grading the mined

landscape to the approximate original contour, use of adequate amounts of—and quality of—coversoil and development of *in situ* soil treatments at sites where coversoil resources were absent have all provided means to establish a diverse plant community. Techniques have been developed to revegetate and stabilize slopes approaching a 50% gradient, which is an asset for mines located in mountainous terrain. Methods to control and treat AMD from open pit mines continue to improve, but this impact to surface water resources is unresolved. Further research is required to develop better AMD treatment methods.

Mine Soils: Reclamation and Soil Carbon Sequestration

Vasant A. Akala

Ohio State University, Columbus, Ohio, U.S.A.

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Soil organic carbon (SOC) sequestration can be an environmentally friendly use of reclaimed minelands, and long-term carbon storage in such systems can offset part of the carbon dioxide emissions. The formation of primary organomineral complexes is the first step in the process of SOC sequestration. Soil aggregation and humification in reclaimed minelands can be higher than the undisturbed sites, resulting in high SOC sequestration. Pasture with topsoil application can achieve the highest SOC sequestration in a short period of time.

INTRODUCTION

The revegetation of mined lands is one of the management options for mitigation of the negative impacts of mining. The area of minelands that have been reclaimed since 1970 is 1 Mha in the United States alone.^[1,2] Land restoration measures can reverse the degradation trends, leading to positive changes in the ecosystem. These include improved water, air, and soil qualities and the attendant socioeconomic benefits.^[3] An important ancillary benefit of mine-land reclamation is its potential to sequester soil organic carbon (SOC).^[4] The potential for sequestration of carbon (C) in the aboveground biomass and minesoils of reclaimed minelands may be high and merit serious consideration as a significant benefit of restoration of highly disturbed land.

MINESOIL DEVELOPMENT AND SOC SEQUESTRATION

The rate of formation of minesoil or minesoil development over time may be the single most important edaphic factor determining the success of the reclamation plan. The rate of minesoil development is a function of reclamation plan management. Freshly exposed mine spoil may be thought of as soil at time zero, in respect to formation, because it consists only of rock and pulverized rock material.^[5] Mine spoils reflect the properties of the parent material more closely than natural soils because of the initial stage of pedogenic development.^[6]

Although there are different theories regarding the rate of minesoil development, there is a general consensus that soil weathering is rapid in the early stages of reclamation, and the rate of change decreases over time.^[7–9] Very rapid chemical reactions occur in spoil as the exposed material

begins to come into equilibrium with its new environment.^[7] Also, minesoils are exposed to processes of physical weathering, such as cycles of wetting and drying, freezing and thawing, and mechanical disruption by roots.^[9] Rapid changes in particle size distribution take place as spoil material weathers.^[10]

The potential of SOC enhancement in minelands depends on biomass productivity, root development in subsoil, and changes in minesoil properties resulting from overburden weathering.^[11] Improvement in soil aggregation is an important factor influencing minesoil development.^[12,13] The changes in minesoil properties impact on biomass productivity and pedogenic processes that lead to SOC sequestration in minesoils. Soil processes that are important in the C dynamics of minesoils and those that lead to SOC sequestration are weathering, stable structure formation, erosion, compaction, aeration, aggregation, nutrient recycling, humification, and mineralization. [Table 1](#) shows how some of these processes relate to SOC sequestration in minesoils.

CASE STUDY

Akala and Lal^[14] conducted a study on a chronosequence of reclaimed minelands, where the effects of reclamation duration (time), land use (pasture and forest, with and without topsoil application), and soil processes (aggregation and humification) on SOC sequestration were observed. The study showed that soil disturbance by mining resulted in high loss of the antecedent SOC pools and reclamation of mined lands regained SOC. Temporal changes in the SOC pool of reclaimed minesoils showed that the potential to sequester SOC was high. The SOC pool of the soil surface (0–15 cm depth) during the initial phases of reclamation

Table 1 Minesoil processes and SOC sequestration.

Processes	Relation to SOC sequestration
Weathering	Formation of soils from the geologic material in the soil reduces the particle size of rock and coarse fragments, leading to the formation of stable peds and aggregates.
Erosion	Probably, the most important process to be addressed in the initial stages of reclamation because the topsoil is susceptible to erosion. Control of erosion in the initial phases assures establishment of vegetation and favorable impact on environmental quality.
Aggregation	Increasing clay and organic matter content favor the eventual formation of minesoil peds and minesoil structure. The presence and development of minesoil structure by aggregation lead to SOC sequestration. Indirectly, aggregation reduces erodibility and increases pore space, thereby increasing infiltration and permeability, and thus improving minesoil quality.
Compaction	Vehicular traffic involved in implementing the reclamation plan causes compaction. This result in increased density and soil strength and decreased aeration of the regraded spoil material. As a result of these changes, permeability is reduced and root proliferation and rooting depth are reduced. Water erosion may also be accelerated.

was 10–15 Mg ha⁻¹, which increased to 45–55 Mg ha⁻¹ in 25–30 years (Fig. 1). The low SOC pool during the initial phases of reclamation was attributed to the drastic disturbance caused by mining. Soil that was removed and stored was applied during reclamation lost significant amounts of SOC by decomposition and erosion during mining. Reclamation, minimum perturbation, and management of restored ecosystems, over a period of 20–25 years, had an ameliorative effect on minesoils because of decreases in

**Fig. 1** Change in SOC during reclamation over time.

soil compaction (reduction in soil bulk density), improvement in soil structure (high aggregation), and increases in SOC accumulation (enhanced biomass productivity). The SOC pool for 15–30 cm depth also increased over the period of reclamation. Possible mechanisms of C sequestration in reclaimed mineland were development of an A horizon, increased aggregation through the formation of organomineral complexes, and humification of soil organic matter (SOM).

Minesoil aggregation and C sequestration are closely related. Akala and Lal^[14] observed a high correlation between water stable aggregates and SOC content. Land disturbance caused by mining not only decreased SOC content of the soil aggregates (secondary organomineral complexes) but also caused a drastic decrease in SOC content associated with the primary soil particles (primary organomineral complexes). The loss in SOC content (in comparison to the antecedent levels in control sites) was 65% in the clay fraction, 75% in the silt fraction, and 40% in the sand fraction. The temporal increase in SOC content in all particle size fractions over the reclamation duration reflected the increase in total SOC pool. The increase (difference in SOC contents between the end and beginning of reclamation period) was 3 to 6 times the antecedent level for the clay and silt fractions and 1 to 2 times for the sand fraction. A large increase in the clay fraction showed the reactive nature of minesoils and its ability to respond to changes in SOC pool. The reactive nature of the primary particles coupled with the increase in SOM input was the most important factors for SOC sequestration in the initial stages of mineland reclamation.

DISCUSSION

The rates of SOC sequestration in reclaimed minelands can be 2–3 Mg ha⁻¹ yr⁻¹ for 0–15 cm depth and 1–2 Mg ha⁻¹ yr⁻¹ for 15–30 cm depth and are higher than those observed in other land uses. For example, SOC sequestration rates by adoption of conservation tillage are in the range of 0.1–0.5 Mg ha⁻¹ yr⁻¹ in temperate regions and 0.05–0.2 Mg ha⁻¹ yr⁻¹ in tropical regions.^[15] Similarly, SOC sequestration rates are in the range of 0.3–0.5 Mg ha⁻¹ yr⁻¹ by restoration of wetlands.^[16] Rates of SOC sequestration reported above can be sustained for a period of 10–15 years. The rate of change of SOC pools or SOC sequestration in reclaimed minelands depends on the magnitude of loss by perturbation (mining) and how far the reclaimed sites are from attaining the equilibrium SOC level. Soils that initially have low SOC content and those that are converted to restorative land management have a potential SOC sink capacity. Reclaimed minelands are an example of such aggrading ecosystems.

The SOC pool that can be potentially attained in reclaimed minelands in the United States is 25 million metric tonnes C.^[15] The net emission of carbon dioxide (CO₂)

increased from 1037 Tg (1 Tg = 1 Teragram = 1×10^{12} g = 1 million metric ton) C equivalent in 1990 to 1263 Tg C equivalent in 1996 in the United States.^[17] Assuming that the reclaimed minelands were at least 25 years old, they had a potential to offset 4% of CO₂ emissions for the United States. The importance of this potential may be realized when considered in combination with the restoration of all degraded soils and ecosystems and in the context of other soil management strategies.^[15]

CONCLUSION

1. The potential to sequester SOC in reclaimed minelands is high at 2–3 Mg ha⁻¹ yr⁻¹.
2. SOC sequestration can be an environmentally friendly use of reclaimed minelands, and long-term C storage in such systems can offset part of the CO₂ emissions (2–4%).
3. The formation of primary organomineral complexes is the first step in the process of SOC sequestration.
4. The total SOC content of the 25–30-year-old-reclaimed sites can be 30–35% higher than that of the undisturbed sites, but not all of the SOC are sequestered in the secondary organomineral complexes, thereby making it vulnerable to future land disturbance.
5. Soil aggregation and humification in reclaimed minelands can be higher than the undisturbed sites, resulting in high SOC sequestration.
6. Pasture with topsoil application can achieve the highest SOC sequestration in a short period of time.

Minerals: Amorphous

April L. Ulery

Agronomy and Horticulture, New Mexico State University, Las Cruces, New Mexico, U.S.A.

Abstract

The term amorphous literally means “without form” and refers to a class of materials that are non-crystalline or, at best, poorly crystalline. Amorphous materials do not have a regular or repeating, ordered, internal atomic structure that is detectable by X-ray diffraction. Mineralogists use X-ray diffraction as the criterion for crystallinity and to identify most inorganic solids. Other terms used to define amorphous materials include short-range-order or X-ray amorphous minerals because the distances between repeating, internal patterns are too short to diffract X-rays.

INTRODUCTION

Crystalline minerals, in contrast to amorphous or non-crystalline materials, have long-range-order, usually in 3-D, and diffract X-rays from repeating atomic planes. Instead of a sharp boundary between amorphous and crystalline materials, a continuum exists between perfectly ordered, highly crystalline minerals and disordered, poorly crystalline to amorphous, non-crystalline solids (Fig. 1).

VARIETIES OF AMORPHOUS MINERALS

Amorphous soil minerals include oxides and hydroxides of aluminum, silicon, iron, titanium, and manganese and silicates of aluminum and iron. They may be hydrated weathering products of primary minerals or unweathered volcanic glass and biogenic silica (SiO_2) phytoliths. Amorphous weathering products occur as coatings or gel hulls on larger mineral grains and as aggregates or discrete particles in the soil clay fraction ($< 2 \mu\text{m}$ equivalent diameter). Glass particles and phytoliths are often larger than $2 \mu\text{m}$ in diameter, and, compared to the smaller amorphous soil components, are not as reactive.

Allophane, as a general term, has previously been used to describe any amorphous aluminosilicate in soils derived from volcanic material. Allophane ($1\text{-}2\text{SiO}_2\text{Al}_2\text{O}_3\cdot n\text{H}_2\text{O}^+$) is recognized as a soil mineral group with a range in alumina and SiO_2 composition and specific diagnostic properties. Imogolite $[(\text{OH})\text{SiO}_3\text{Al}_2(\text{OH}_3)]$ is a mineral with threadlike or tubular morphology and long-range order in only 1-D. Although it exhibits unique diffraction characteristics, it is often included in the discussion of amorphous minerals because it has similar chemical and physical properties with allophane and is often associated with allophane in soils.^[1] For more detailed information on allophane and imogolite, please see the section “Allophane” in this encyclopedia.

Poorly crystallized halloysite ($\text{Al}_2\text{Si}_2\text{O}_{10}\text{OH}_4\cdot n\text{H}_2\text{O}$) is another aluminosilicate that is included in the group of amorphous minerals because of its broad X-ray diffraction bands and tubular or curling morphology. Hisingerite ($\text{Fe}_2\text{O}_3 \cdot 2\text{SiO}_2\cdot n\text{H}_2\text{O}$) is a “very finely crystalline” to amorphous variant of iron phyllosilicates or an iron silicate analog of allophane. Other iron minerals observed in soils but amorphous to X-rays include ferrihydrite ($5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$) and feroxyhite (FeOOH). Ferrihydrite may exist anywhere along the continuum between crystalline to poorly crystalline. It can range from having short-range order in 3-D to less order in only 2-D.^[2] Poorly crystalline varieties of aluminum and titanium are also identified as pseudomorphs of their corresponding well-ordered minerals. They include pseudoboehmite (AlOOH) and pseudorutile ($\text{Fe}_2\text{O}_3\cdot n\text{TiO}_2\cdot m\text{H}_2\text{O}$). Amorphous varieties of manganese oxides have not been specifically named.

SiO_2 may be present in soils as one or more mineral varieties along a continuum that ranges from well-ordered through disordered to no atomic order (Fig. 1). Quartz and cristobalite (opal-C) represent the well-ordered, crystalline phases of SiO_2 , whereas biogenic opal (opal-A) and volcanic glass are non-crystalline hydrous SiO_2 compounds. Short-range-ordered to disordered cristobalite (opal-CT) is also found along the SiO_2 continuum. Biogenic opaline phytoliths and diatoms are valuable indicators of paleoenvironments and are identified by the morphology of the biological structure in which they originated. However, both SiO_2 phytoliths and glass from pyroclastic deposits are amorphous.^[3] SiO_2 is not as chemically reactive as other amorphous minerals, but it is important as a cementing agent in arid zone soils.

PROPERTIES OF SOILS CONTAINING AMORPHOUS MINERALS

Soils derived from volcanic ash are called Andisols and contain the highest amounts of amorphous components.

Fig. 1 A comparison of three SiO₂ varieties plotted along the crystallinity continuum. The X-ray peak positions are in nanometers, and the spectra were made using CuK α radiation. Note that the well-ordered quartz is typically purer than either the opal-CT or opal-A, which both may contain numerous impurities in the lattice structure.

Spodosols are soils with a diagnostic subsurface horizon containing up to 50% iron and aluminum hydrous oxides (a significant portion of which may be amorphous) and organic matter in the clay fraction. Hydrous iron and aluminum oxides, SiO₂, and kaolin minerals, some of them amorphous or poorly crystalline, dominate in oxic horizons, diagnostic for Oxisols. Even though in most soils amorphous materials comprise a relatively small part of the total mass, they contribute significantly to the physical and chemical properties of the soil.^[4]

Physical Properties

Amorphous materials are extremely important both physically and chemically because of their small particle size, large surface area, and reactive surface chemistry (Table 1). The surface area of amorphous minerals represents a large pool of active sites that can interact with cations, anions, and water to aggregate soil particles by forming bridges and

coatings. Large surface areas result from the tiny diameters of individual tubes or spheres of many amorphous materials and are several times higher than most crystalline soil minerals.

Amorphous materials strongly influence bulk density, aggregate stability, water holding capacity, and plasticity. Soils containing large amounts of amorphous materials have bulk densities ranging from 0.3 to 1.0 Mg m⁻³.^[5] In contrast, most mineral soils have bulk density values from 1.2 to 1.7 Mg m⁻³. Low bulk density and high void ratios are largely due to the formation of stable, porous aggregates by amorphous materials and the inability of lightweight glass shards and porous minerals to be compacted. Soils high in amorphous materials have void ratios ranging from 2 to 5, whereas sandy alluvial soils have values of 0.8 to 1.0 and clayey soils have values ranging from 1.5 to 2.5. These soils also exhibit large preconsolidation loads and anomalous compaction behavior.^[5]

Table 1 Ranges of selected physical and chemical properties of amorphous minerals.

Mineral	Particle			Surface area (m ² g ⁻¹)	CEC ^a (cmol _c kg ⁻¹)
	Density (Mg m ⁻³)	Diameter (nm)	Morphology ^b		
Allophane	2.7–2.8	3–5	Spherical	100–800	5–350
Ferrihydrite	2.4–3.8	3–7	Coatings/spherical	200–600	10–160
Halloysite	2.5–2.6	20–200	Tubular/spherical	10–45	10–40
Imogolite	2.6–2.8	10–30	Threadlike	700–1100	19–37
Opaline SiO ²	1.5–2.3	10–50	Spherical ^c	40–120	<10

^aCEC is strongly pH-dependent for most amorphous minerals and increases as the pH increases.
^bShape most commonly observed; others also may be reported.
^cAmorphous SiO₂ also exists as phytoliths, spicules, or shards visible to the naked eye (mm in length).

Fig. 2 Schematic representation of a soil aggregate stabilized by amorphous coatings surrounding larger primary minerals, biomass and connecting layers of clay-humus.

Stable aggregates are formed during the drying of soils rich in amorphous minerals. Amorphous or gel-like material-coating soil particles cements those particles into larger aggregates (Fig. 2). The amorphous coatings behave as viscous bodies when moist and elastic bodies when dry.^[6] The high content of organic matter commonly associated with amorphous materials also contributes to enhanced aggregate formation and stability and darkens the soil (in Japanese *ando* = black).

The moisture content of amorphous-rich or volcanic soils is much higher than that of other soils and ranges from 80% to 180% on an oven-dried basis.^[5] The high natural moisture content contributes to low bulk density values, which are based on dry soil weight per volume. The total porosity of many amorphous minerals and the aggregates they form provides numerous sites for water storage. Once dried, however, these minerals and soils tend to rehydrate incompletely.^[5] The irreversible wetting of these soils and minerals affects several physical and engineering properties including liquid and plasticity limits and water retention values.

Chemical Properties

Amorphous minerals have numerous molecular units, or surface functional groups, that when charged can affect organic matter retention, soil fertility, and the mobility of metals and organic compounds. Anion and cation exchange capacities (AEC and CEC) are variable for most amorphous minerals depending on solution pH and ionic composition. The pH-dependent or amphoteric charge tends to be positive at low pH and negative above the point of zero charge, which varies for each mineral but is usually between 3 and 7. Thus, AEC is typically higher at low pH, and CEC increases as the pH increases.

Because of the variable nature of surface charge on amorphous materials, the pH and method of analysis strongly influence the CEC and AEC values. Sample drying, solution concentration, temperature, pH, and mineral composition all affect CEC and AEC values.^[5] The CEC for individual amorphous minerals varies

widely (Table 1). Amorphous components, even in small amounts, contribute to the variable CEC and AEC in soils. For example, smectite-rich clayey soils containing 4–32% amorphous material had CEC values ranging from 24 to 300 cmol_c kg⁻¹.^[7]

Soil fertility and nutrient availability problems often arise in soils rich in amorphous materials. Strong covalent and ionic bonds form between oxyanions and amorphous mineral surfaces, especially under acidic conditions. The oxyanions, which include nutrients such as phosphate, sulfate, and molybdate or contaminants like selenite and arsenate, may be fixed or permanently adsorbed on the solid phase, which removes them from solution and makes them unavailable to plants. Anion exchange, precipitation reactions, and physical adsorption are other mechanisms that also remove oxyanions from soil solution.

IDENTIFICATION AND CHARACTERIZATION OF AMORPHOUS MINERALS

There is not a specific method universally accepted for the chemical characterization of soil amorphous minerals.^[8] The techniques used to identify and quantify amorphous components include selective dissolution, electron microscopy, differential thermal analysis and loss on ignition, differential X-ray diffraction, X-ray fluorescence, and infrared spectroscopy.

The most common method used to measure the chemically active portion of the amorphous fraction is extraction with acid ammonium oxalate in the dark.^[9] Following the extraction of non-crystalline aluminosilicates and hydrous oxides, boiling in 0.5 M sodium hydroxide or potassium hydroxide is used to remove amorphous SiO₂. It is useful to pretreat soil samples using one or both of these methods to clear the crystalline minerals of amorphous materials that coat, dilute, or otherwise interfere with the crystalline components of soil.^[9] Among several methods estimating the amorphous content of soils, it appears that the Rietveld method is one of the best to determine the total amorphous content of the clay fraction.^[8] For a variety of quantitative methods in soil mineral analysis, including amorphous components, the reader is referred to the work of Amonette and Zelazny.^[10]

CONCLUSION

Amorphous or non-crystalline minerals are atomic structures with short-range order to no order. Most amorphous minerals are extremely small and reactive both chemically and physically. They can exist as discrete particles and aggregates, but are most common as coatings on other soil particles. As coatings, they aid in the formation of aggregates, crusts, duripans, or other cemented features in soils. Soils high in amorphous minerals usually have high water

holding capacity, low bulk densities, and high void ratios. They also have slippery but non-sticky consistence, high Atterberg limits, greater values for liquid and plastic limits on undried than on dried samples, large preconsolidation loads, and anomalous compaction behavior.^[5] Amorphous minerals have large organic matter retention capability and pH-dependent ion exchange capacities. Phosphate, sulfate, and other ions or metals are commonly fixed by amorphous soil minerals.

Minerals: Primary

Nikolaos I. Barbayiannis

Aristotle University of Thessaloniki, Thessaloniki, Greece

Vissarion Z. Keramidas

Laboratory of Soil Science, School of Agriculture, Aristotle University of Thessaloniki, Thessaloniki, Greece

Abstract

Primary minerals identified in soils belong mainly to the classes of silicates, oxides of iron, zirconium, and titanium, and phosphates and are usually found in the sand and silt fractions. In soils, they are inherited from the parent material, and their presence is predicated by the nature of the mineral and the intensity of weathering, which results in the formation of secondary clay minerals in soils and the release of elements, essential for plant growth, in the soil solution. Therefore, primary minerals play a significant role in soil formation, and in the long run, they serve as sources of plant nutrients.

INTRODUCTION

According to the *Glossary of Soil Science Terms*,^[1] primary minerals are those that have not been altered chemically since their deposition or crystallization from molten lava (magma). Primary minerals identified in soils belong mainly to the classes of silicates, oxides of iron (Fe), zirconium (Zr), and titanium (Ti), and phosphates (apatite, $[\text{Ca}_{10}(\text{PO}_4)_6(\text{Cl}, \text{F}, \text{OH})_2]$). Their study is essential because: 1) they serve as sources of plant nutrients; 2) they are, in certain cases, the precursors of secondary clay minerals; and 3) they provide information about soil development.

SILICATES

Of the primary minerals found in soils, silicates are the most abundant, comprising nearly 40% of the common minerals. The building unit of the silicates is the silicon (Si) tetrahedron. Silicate structures may consist of single tetrahedron (nesosilicates), double tetrahedra (sorosilicates), rings (cyclosilicates), single or double chains (inosilicates), sheets (phyllosilicates), or framework patterns (tectosilicates). Typical silicate minerals most likely to be found in soils are presented in [Table 1](#).

Olivines

Olivines are olive green nesosilicates in which divalent cations mainly Mg^{2+} and Fe^{2+} join the Si tetrahedra by forming octahedra of Mg^{2+} or Fe^{2+} . The forsterite–fayalite series include the most abundant naturally occurring olivines, with Mg^{2+} and Fe^{2+} being the respective cations of the series end members.

Olivines are the first minerals to crystallize in the initial stages of magma solidification, and they are highly unstable minerals because the high ratio of the divalent cations to Si in its structure renders them vulnerable to chemical attack. Therefore, olivines are very easily weathered in soils, and for this reason, they are considered relatively rare soil constituents and can be found only in very young soils and in the coarser sand fractions.

Zircon

Zircon is another nesosilicate mineral. Its structure consists of alternating edge-sharing Si tetrahedra that are held together with Zr^{4+} ions that are located in the center of triangular dodecahedra.^[3]

Zircon is found as residual grains in the sand and silt fractions of soils, and because of its stability in pedogenic environments, it is frequently related to the degree of soil development and soil age.

Pyroxenes and Amphiboles

Pyroxenes and amphiboles are “ferromagnesian” minerals with single- and double-chain structures, respectively ([Table 1](#)). Pyroxene chains have Si tetrahedra sharing two oxygen (O) atoms. In amphiboles, the chains are formed by Si tetrahedra sharing alternatively two and three O atoms. In both classes of minerals, the chains are held together mainly by divalent cations (e.g., Mg^{2+} , Fe^{2+} , or Ca^{2+}) located at the center of an octahedron.^[4]

Augite and hornblende are the most important minerals of the pyroxenes and amphiboles, respectively. Pyroxenes and amphiboles are formed at lower temperatures and

Table 1 Common primary minerals of the silicate class found in soils.

Silicon tetrahe- dra arrangement	Name of mineral or group	Ideal formula
Nesosilicates (SiO ₄) ⁴⁻ (single)	Olivine	(Mg,Fe) ₂ SiO ₄
Zircon	ZrSiO ₄	
Sorosilicates (Si ₂ O ₇) ⁶⁻ (double)	Epidote	Ca ₂ (Al,Fe)Al ₂ O (SiO ₄) ₄ (Si ₂ O ₇)(OH)

pressures during magma solidification compared to olivines and are more stable in the weathering environment. In soils, however, they weather relatively faster and are largely confined in the sand and silt fractions. Some of them may occur in the clay fraction of soils that are young and have not been subjected to intensive weathering. [5]

Feldspars

Feldspars are tectosilicates, with 3-D framework of corner-linked Si and aluminum (Al) tetrahedra. The Al tetrahedral result from Al substitution for Si and the charge deficit created is compensated by sodium (Na), potassium (K), and calcium (Ca). Feldspars are virtually present in all sediments and soils in quantities that vary with the nature of the parent material and the stage of weathering. The majority of feldspars belong to the ternary system NaAlSi₃O₈ (albite)–KAlSi₃O₈ (K-feldspar)–CaAl₂Si₂O₈ (anorthite). In K-feldspars, one of every four Si is replaced by Al, with K balancing the charge. Most common K-feldspars are sanidine, orthoclase, microcline, and adularia. Na and Ca feldspars form a series called “plagioclase”

with compositions ranging from pure albite (Na-feldspar) to pure anorthite (Ca-feldspar).

The presence of feldspars in soils is related to the overall mineralogical composition and the prevailing environmental conditions, including climate, topography, degree of leaching, the presence of chelating agents, redox status, and soil solution composition. [6]

Feldspars usually follow the stability sequence: anorthite < albite < K-feldspars. [3]

Weathering of plagioclase minerals increases the supply of Ca in soils in a manner similar to that of weathering of K-feldspars in the clay, and silt fractions provide an important source of K in soils.

Micas

Micas are 2:1 phyllosilicate minerals formed by two Si tetrahedral sheets and an Al octahedral sheet in between. One of four Si in the tetrahedral sheet is replaced by Al, and the high negative layer charge developed is balanced by non-hydrated interlayer cations that hold the layers tightly together. [7] The most abundant and important micas in soils (muscovite and biotite) have K as the interlayer cation, which upon weathering is released in the soil solution and serves as a plant nutrient.

Micas are formed in soils from the parent material, and as they tend to weather to other minerals, they are expected to prevail in younger, less weathered soils. [8] In young soils, they tend to occur as discrete sand and silt particles, while in more weathered soils they are usually found in the clay fraction. Biotite is uncommon in most soils because it is transformed very easily to other secondary minerals, even under mild weathering conditions. Muscovite is commonly found in soils of advanced weathering.

Like the other primary minerals in soils, mica becomes unstable in the weathering conditions at the soil surface. This is demonstrated by the fact that biotite is almost absent from the surface horizons of most, except very young, soils. Micas are considered as the precursors of several secondary 2:1 minerals and clay minerals in soil like illites, vermiculites, and smectites. [8,9]

Quartz

Quartz is one of the seven polymorphs of silicon dioxide, found in soils and sediments: quartz, cristobalite, tridymite, coesite, stishovite, lechatelierite (silica glass), and opal. [10] Quartz and disordered cristobalite are the typical forms found in soils, while tridymite is present mostly in soils developed from siliceous volcanic rocks.

Quartz belongs to the tectosilicate class of the silicate minerals (Table 1), which have each O of Si tetrahedra linked to Si atoms of adjacent tetrahedra, forming a 3-D framework structure. Owing to its resistance to weathering, quartz is generally concentrated in the sand and silt fractions, and generally eluvial (surface) horizons are enriched owing to weathering and removal of less resistant minerals.

Quartz is considered as inert skeletal material and exhibits very small to nil anion and cation exchange properties. In certain horizons, however, poorly crystalline quartz and other silica minerals may serve as cementing agents. In normal soils, quartz particles are also considered as important components of the soil structure because they are linked together or to clay domains through organic matter bridges.^[11] Quartz is also a suitable mineral to assess parent material uniformity and degree of weathering because of its abundance, resistance to weathering, and immobility.

OXIDES

Fe

Of the several Fe oxides and hydroxides found in soils, magnetite (Fe_3O_4) is the only one of primary origin. The crystal structure of Fe_3O_4 , like all Fe oxides, consists of Fe ions surrounded by six O in a sixfold coordination.

Fe_3O_4 occurs as black grains in the heavy fraction of the sand and silt fraction of soils and is of lithogenic origin.^[12] As Fe_3O_4 is found in the coarser soil fractions and is easily transformed to maghemite in the finer fractions, its influence on soil chemistry is minor.

Ti

Rutile (TiO_2) and ilmenite are the main primary Ti minerals found in soils. TiO_2 is tetragonal and consists of TiO_6 polyhedra that share their opposite edges and form chains along the c-axis.

Ti oxides are common accessory minerals of igneous and metamorphic rocks and have been identified in the sand and silt fractions of soils originating from such rocks.

TiO_2 develops a negative charge through adsorption of OH^- on surface Ti ions. This charge is pH dependent. Charge development plays an important role in sandy acid soils and influences physical and chemical properties such as formation of stable aggregates and retention of nutrients such as phosphate.

Ti oxides, in the similar way as zircon, are most frequently related to soil genesis studies. Their occurrence in the non-clay fraction in the different horizons of soils and the parent material provides information about the profile uniformity and soil development.

PHOSPHATES

Phosphate minerals comprise only a small part of the inorganic fraction of soils, and their basic structural unit is the orthophosphate ion (PO_4^{3-}), which forms a tetrahedron where phosphorous (P) is surrounded by four O^{2-} . The high affinity of PO_4^{3-} for cations forms structures that are classified as framework, chain, and layer phosphates, similar to silicates.^[13] $[\text{Ca}_{10}(\text{PO}_4)_6(\text{Cl},\text{F},\text{OH})_2]$ is the most frequently

reported phosphate of igneous origin and has been identified with photographic microscopy as discrete grains in the sand and silt fraction of a number of soils. Along with their weathering products, apatites are considered as a natural source of P for plants.

CONCLUSION

Primary minerals identified in soils belong mainly to the classes of silicates, oxides of Fe, Zr, and Ti, and phosphates and are usually found in the sand and silt fractions. In soils, they are inherited from the parent material, and their presence is predicated by the nature of the mineral and the intensity of weathering, which results in the formation of secondary clay minerals in soils and the release of elements, essential for plant growth, in the soil solution. Therefore, primary minerals play a significant role in soil formation, and in the long run, they serve as sources of plant nutrients.

Minerals: Secondary

Deborah A. Soukup

Geomatrix Consultants, Inc., Bakersfield, California, U.S.A.

Abstract

This entry presents a broad overview on the formation and characteristics of common secondary minerals in soils. The alteration pathways occurring in the soil environment are very complex and are influenced by a variety of abiotic and biotic factors. The secondary minerals discussed in this entry may also occur in soils as a result of inheritance from parent materials.

INTRODUCTION

There are three possible origins for minerals in soil environments including inheritance from parent materials, weathering transformations of existing minerals, and neoformation or crystallization from solution.^[1] Secondary minerals are defined as minerals formed later than the rock enclosing them, usually at the expense of an earlier-formed primary mineral, as a result of weathering, metamorphism, or solution.^[2] Alternatively, secondary minerals may be defined as recrystallized products of the chemical breakdown and/or alteration of primary minerals.^[3] Secondary minerals are generally characterized by smaller particle size, because the particle size of primary minerals is decreased during weathering and release of soluble materials. Therefore, secondary minerals are typically principal components of the silt and clay fraction of soils.^[4]

TYPES OF SECONDARY MINERALS IN SOIL

The major secondary minerals and the soil orders in which they commonly occur are listed in [Table 1](#). Primary minerals including feldspars, pyroxenes, amphiboles, micas, and primary chlorite may be altered to secondary minerals such as illite, vermiculite, clay chlorite, smectites, kaolinite, halloysite, and oxides of iron (Fe) and aluminum (Al) by the removal of silica and bases, and the addition of water. Additional details and the significance of these secondary minerals in soil environments are discussed in the following sections. Selected physical and chemical characteristics of the secondary minerals are summarized in [Table 2](#).

Iron and Aluminum Oxides

The most common oxides of Fe and Al, typically reported in soils, are goethite, hematite, and gibbsite.^[4,6,8] These minerals, sometimes referred to as *sesquioxides*, generally occur in soils subject to intense weathering, e.g., Oxisols

and Ultisols. The sesquioxide minerals are amphoteric in character and exhibit variable charges. These minerals are also characterized by high surface charge density, high specific surface area, and high cation and anion adsorption capacity.^[4–9] Additionally, sesquioxide minerals are reported to enhance soil aggregation. Finely divided iron oxides are believed to act as binding agents among other soil particles and may result in cementation of these particles into large units.^[6]

Even at low concentrations, the iron oxides goethite and hematite play an important role in influencing soil color because of their pigmenting power.^[6] Goethite minerals are naturally yellow, whereas hematite is bright red. In fact, the greater pigmenting power of hematite can mask the yellow color of higher concentrations of goethite. Gibbsite, in contrast, is colorless; however, its content is used in the oxidic ratio to indicate the relative degree of weathering

$$\text{Oxidic ratio} = \frac{(\% \text{ extractable Fe}_2\text{O}_3 + \% \text{ gibbsite})}{\% \text{ clay}} \quad (1)$$

If the oxidic ratio is 0.2, the soil is considered to be highly weathered.

Kaolinite and Halloysite

Kaolinite is one of the most common clay minerals in soils, particularly those of warm, moist climates. Kaolinite is a 1:1 aluminosilicate mineral composed of one octahedral sheet stacked above one tetrahedral sheet. The two crystal units comprising one kaolinite particle are held together by hydrogen bonds, and the space between the structural layers, therefore, has a fixed dimension.^[4,11] Halloysite is also a 1:1 aluminosilicate mineral with the same composition as kaolinite, except that halloysite may be hydrated and contain water between the structural layers. Both kaolinite and halloysite are products of acid weathering, but halloysite is formed more rapidly in soils of volcanic origin.

Kaolinite and halloysite typically have low surface areas and low cation exchange capacity (CEC) and anion

Table 1 Ideal chemical formula of secondary minerals commonly occurring in soils.

Mineral name	Chemical formula	Major occurrences
Oxides of Fe and Al		
Goethite	FeOOH	Oxisols, Ultisols
Hematite	Fe ₂ O ₃	Oxisols, Ultisols
Gibbsite	Al(OH) ₃	Oxisols, Ultisols
Aluminosilicate clays		
Kaolinite	Al ₂ Si ₂ O ₅ (OH) ₄	Ultisols, Oxisols, Alfisols
Halloysite	Al ₂ Si ₂ O ₅ (OH) ₄ ·2H ₂ O	Andisols
Illite	K(Si ₃ Al)(AlMg) ₂ O ₁₀ (OH) ₂	Alfisols, Mollisols
Chlorite ^a	[(M ²⁺ , M ³⁺) ₃ (SiAl) ₄ (Al ₂)O ₁₀ (OH) ₂] ^{x-} [(M ²⁺ , M ³⁺) ₃ (OH) ₆] ^{x+}	Common accessory mineral in many soils
Vermiculite	Mg(SiAl) ₄ (Al ₂)O ₁₀ (OH) ₂	Common in many soils
Smectite	Na(Si ₄)(AlMg) ₃ O ₁₀ (OH) ₂	Vertisols, Mollisols, Alfisols
Hydroxy-interlayer Vermiculite and Smectite	Chemical composition highly variable	Wide geographic distribution but most abundant in Ultisols and Alfisols
Carbonate and sulfate minerals		
Dolomite	CaMg(CO ₃) ₂	Aridisols, Mollisols, Alfisols, arid Entisols
Calcite	CaCO ₃	Aridisols, Mollisols, Alfisols, arid Entisols
Gypsum	CaSO ₄ ·2H ₂ O	Aridisols

^aM²⁺ and M³⁺ represent cations with charges of +2 and +3, respectively.

exchange capacity. Isomorphous substitution within the crystal is limited, contributing to the low permanent charge.

Table 2 Selected physical and chemical characteristics of secondary minerals commonly occurring in soils.

Mineral name	Surface area (m ² /g)	CEC (cmol _c /kg)
Oxides of Fe and Al		
Goethite ^a	50–200	3
Hematite ^a	50–200	3
Gibbsite ^b	58 > 600	1–3
Aluminosilicate clays		
Kaolinite	5–39	2–15
Halloysite	21–43	10–60
Illite	80–150	20–40
Chlorite	25–150	10–40
Vermiculite	600–800	100–200
Smectite	600–800	80–150
Hydroxy-interlayer Vermiculite and Smectite	25–150	CEC varies depending on degree of filling of interlayer space
Carbonate and sulfate minerals		
Dolomite ^c		
Calcite ^c		
Gypsum ^c

^cSee Doner & Lynn^[10] for additional information.

However, kaolinite and halloysite may develop variable or pH dependent negative charge because of the dissociation of protons for exposed OH groups.^[4,11] The typical range in CEC for kaolinite and halloysite is from 1 to 10 cmol(+)/kg.

Kaolinite-containing clays are used extensively in the production of brick, sewer pipes, and drain tiles. Kaolinite is also used in the ceramic industry, because of its low expansion and contraction capacity. Additionally, kaolinite is used for the production of false teeth, paper making, and in the pharmaceutical industry.^[4,11]

Illites

Illites are micaceous clays and have been referred to as *hydrous micas* and *hydrobiotite*.^[4] However, illite differs from micas, such as muscovite, in that it contains more silicon dioxide and less potassium (K). Illites are 2:1 aluminosilicate minerals consisting of one octahedral sheet sandwiched between two tetrahedral sheets. The 2:1 layers are bound together strongly by K ions, and thus, illites are non-expansive and do not exhibit shrink–swell behavior upon wetting and drying.^[4,12] Illite typically weathers to smectite under conditions of high precipitation, because of the loss of interlayer K.

Vermiculites

Vermiculite is also a 2:1 aluminosilicate mineral with magnesium (Mg) occupying the octahedral positions between the two tetrahedral sheets.^[4,13] Vermiculites are common weathering products of micas in well-

drained soils and are characterized by high CECs ranging from 144 to 182 cmol(+)/kg.^[13] These minerals exhibit *wedge zones*, attributed to marginal curling of layers on the mineral surface.^[4] These wedge zones provide partially enlarged interlayer spacings in which organic matter may be entrapped, or for fixation of K, NH_4^+ , and other cations. The high fixation capacity of many soils for K and NH_4^+ is primarily attributable to the presence of vermiculite. Vermiculite is also widely used as a potting medium in nurseries and in cat litter.

Smectites

Smectites are a group of expansive, 2:1 aluminosilicate minerals, commonly occurring in soils with impeded drainage and/or in soil environments characterized by high silicon (Si) and basic cation activities.^[14] Minerals within the smectite group are classified based upon the location of the layer charge, either within the tetrahedral or octahedral sheets. In montmorillonite, substitution of Mg for Al in the octahedral sheet produces the layer charge. The layer charges of beidellite and nontronite, two other important smectite minerals, are concentrated in the tetrahedral sheets. The predominant octahedral cations in beidellite and nontronite are Al and Fe, respectively.^[14]

Smectites are generally responsible for the high shrink-swell conditions in soil and result in more damage annually than any other natural disaster including earthquakes and floods. Annual estimates of damage to residential structures in the United States were approximately 798.1 million in 1970 and was projected to increase to 997 million by the year 2000.^[15] These figures increase by a factor of 2–3 if damage to industrial and commercial buildings and transportation infrastructure is included.

Hydroxy-Interlayered Vermiculite and Smectite

Hydroxy-interlayered vermiculite (HIV) and smectite (HIS) are believed to occur in soils as weathering products derived from chlorite or micas or from the deposition of hydroxy-Al or -Fe polymeric components within the interlayer spaces of vermiculite and smectite.^[16] HIV and HIS are widely distributed geographically and are found in several soil orders, although they are most commonly reported in Ultisols and Alfisols.^[16]

There is significant variability in the composition of HIV and HIS, because the composition is dependent on the basic 2:1 mineral structure and the type and amount of hydroxy-interlayer material within the interlayer spaces. The presence of hydroxy-Al and -Fe interlayer components may have a profound effect on some of the physical and chemical properties of HIV and HIS, including swelling, CEC, and adsorption of metals and anions. Many investigators have reported that formation of hydroxy-Al and -Fe interlayers resulted in reduced swelling and dispersion of

smectites. Hydroxy-Al polymers were more effective than hydroxy-Fe polymers in reducing swelling, presumably because the Al interlayer components are more uniformly distributed within the interlayer space, and their greater relative stability.^[16]

The CEC of HIV and HIS may also be reduced as the interlayer space is filled. The primary mechanisms proposed for the observed charge reduction in HIV and HIS compared to the non-interlayered end members are precipitation of Al on surfaces and/or into interlayer spaces, sterically blocking exchange sites, and adsorption of positively charged hydroxy-Al polymers that are non-exchangeable.^[16] Hydroxy-Al interlayers can also prevent fixation of K^+ , NH_4^+ , Cs^+ , and Rb^+ because the interlayer material inhibits collapse of the layers about these ions. Finally, the presence of hydroxy interlayers in 2:1 clay minerals significantly enhances the adsorption of anions, such as P^{3-} .^[16] The increase in anion adsorption in hydroxy-interlayered clays occurs because anions are only adsorbed at edge sites in minerals not containing hydroxyl interlayers.

Chlorites

Chlorites are hydrated Mg and Al silicates that are commonly green in color and resemble micas in appearance.^[4,16] Structurally, chlorite is a 2:2 aluminosilicate mineral consisting of one octahedral sheet and two tetrahedral sheets with the interlayer space occupied by $\text{Mg}(\text{OH})_2$ or brucite layers. The replacement of Mg by Al in the brucite layers creates enough positive charge to nearly neutralize the negative charges. Thus, chlorite has little or no charge and a small CEC. Chlorites are less stable than most of the other clays in acidic environments and are subject to rapid weathering.^[4,16]

Carbonate and Sulfate Minerals

Calcium (Ca) and magnesium carbonate minerals, including calcite and dolomite, may originate from several sources or combinations of sources, either directly in the form of carbonates, or by a solution-precipitation mechanism.^[10] Dissolution of more soluble Ca-bearing minerals, such as gypsum, may result in the subsequent precipitation of calcite. Carbonates may also be formed by the reaction of Ca ions in rainwater and surface water with CO_2 -charged H_2O in the soil. Coatings of calcium carbonate may eventually accumulate and result in cementation in some soils. Movement of clay in calcareous soils has also been reported to be restricted because of flocculation of the silicate clays by Ca^{2+} .^[10]

Gypsum may be precipitated in soil from surface or subsurface waters rich in Ca and SO_4 . It may also be formed through the oxidation of pyrite and subsequent reaction of acid sulfate with CaCO_3 .^[10] Gypsum has frequently been used to reclaim sodic soils because of

its high solubility. However, numerous cases of soil subsidence and deterioration of concrete due to the presence of gypsum have been reported.

CONCLUSION

In summary, it should be noted that the information presented in this entry on the formation and characteristics of common secondary minerals in soils is a broad overview that simplifies many relevant details. The actual alteration pathways occurring in the soil environment are very complex and are influenced by a variety of abiotic and biotic factors. The secondary minerals discussed in this entry may also occur in soils as a result of inheritance from parent materials. Additionally, it may be extremely difficult in some soil environments to determine the precise origin of a given mineral.

Minerals: Solubility

Wayne P. Robarge

Soil Science, North Carolina State University, Raleigh, North Carolina, U.S.A.

Abstract

Minerals are found in almost all soils, and the precipitation and dissolution reactions of minerals are an integral component of the biogeochemical cycles in soils. A mineral is considered a naturally occurring substance, inorganic in composition, with a definite chemical composition and an ordered atomic arrangement. Minerals in soils are divided into two broad categories: primary and secondary minerals.

MINERALS

Primary Minerals

A primary mineral is considered one that has not been altered chemically since its deposition and crystallization as a result of large-scale geological processes.^[1] Soils inherit primary minerals from the parent material from which the soil is derived.^[2] Chemical weathering of primary minerals (a dissolution reaction) represents the release of plant nutrients such as magnesium (Mg), calcium (Ca), potassium, phosphorus (P), iron (Fe), manganese (Mn), and boron for plant uptake and recycling in soil–plant ecosystems. Primary minerals are also a source of trace metals, which can either be essential or toxic to life. As most primary minerals are formed by tectonic activities, they are inherently unstable in soils and will dissolve.

Secondary Minerals

Secondary minerals form from the decomposition and restructuring of primary minerals or from precipitation reactions (formation of a new mineral) involving chemical constituents of primary minerals released during dissolution.^[1] Most secondary minerals in soils are phyllosilicates: silicate-based minerals having sheets of silicate anions linked to sheets of cations [usually aluminum (Al)] to form a layer.^[3] The cations in phyllosilicates also have reacted with oxygen such that the sheets of silicate anions and cations are linked together by sharing oxygen atoms. This yields a very stable structure that resists weathering. Phyllosilicates can be formed in soils or are inherited in the soil parent material, having been formed elsewhere as part of the weathering of primary minerals.^[4]

Additional secondary minerals found in soils include oxides, sulfates, sulfides, carbonates,^[5] and phosphates.^[6] In arid environments, the presence of sulfates and carbonates is common, but they are generally absent from

well-leached soils in humid environments. Most oxides are stable in well-aerated soils and are considered the end product of the decomposition of primary and secondary minerals in highly weathering environments. However, the presence of organic acids derived from the decomposition of plant material can dissolve most oxides in acid soils. Certain metal oxides based on Fe and Mn are readily soluble under reducing conditions induced in poorly drained soils or when soils are temporarily saturated with water. Sulfides are generally not stable in well-aerated soils, due to the conversion of the sulfide anion to sulfate in the presence of oxygen. Sulfides are common in anaerobic soils where there is a source of sulfur either from plant residues or sulfate secondary minerals. Phosphates encompass a wide range of minerals with differing solubility. In neutral and basic soils, the Ca-based phosphates, known as apatites, are relatively insoluble and can remain in soils for long periods of time. In acid soils, Al- and Fe-based phosphates are considered stable, especially in agricultural soils receiving P-containing fertilizers. The names and chemical formula of some common primary and secondary minerals are given in [Table 1](#).

DISSOLUTION REACTIONS OF MINERALS

Solubility of Minerals

The stability of primary and secondary minerals in soil, and therefore their solubility, is directly dependent on their chemical structure and the nature of the weathering environment.^[2] Differences in chemical bonding among minerals influence their shape, often exposing surfaces or defects in the minerals that react more readily with water or serve as points of attack for other constituents in the soil solution. The nature of the weathering environment is expressed through the composition of the soil solution [pH, ionic strength (presence of other cations and anions), presence of ligands, reductants, oxidants, or ions that can adsorb

Table 1 Names, chemical formula, and dissolution reaction for common minerals.

Name	Chemical formula	Dissolution reaction
Carbonates		
Calcite	CaCO_3	$\text{Ca}^{2+} + \text{CO}_3^{2-}$
Dolomite	$\text{MgCa}(\text{CO}_3)_2$	$\text{Mg}^{2+} + \text{Ca}^{2+} + 2\text{CO}_3^{2-}$

^aDissolution of Si-containing minerals often requires H_2O to form the silicate anion: H_4SiO_4 .

onto the mineral surface] and soil drainage, which influences the rate at which constituents released from the mineral surfaces are transported from the local environment.^[7] Acid (H^+) or base (OH^- ; and even water molecules) destroys mineral structures by migrating into the interior of the mineral and breaking the chemical bonds between the mineral's anions and cations. Ligands are inorganic or

organic molecules that have the ability to bind tightly with the cations in minerals and help to remove them from a mineral surface. Reductants and oxidants cause the cations in minerals to change their charge (reductants reduce charge and oxidants increase charge). When a cation within a mineral structure changes charge, it weakens the original structure allowing the attack by acids, bases, or water molecules to be more successful. Soil drainage is important in mineral dissolution because the original ionic constituents of the mineral accumulate in the surrounding soil solution, mineral dissolution will eventually stop or slow significantly. Thus primary and secondary minerals are often found in weathering environments that would favor their relatively rapid dissolution because of poor drainage in the soil.

Chemical theories derived to predict the behavior of minerals in soils and that attempt to account both for differences in chemical structure and the nature of the soil weathering environment have evolved from consideration of either macroscale or microscale processes.^[8] Theories that describe macroscale processes are based on the science of thermodynamics and allow prediction of mineral solubility.^[9] The power of this approach is that a scientist can attempt to predict the presence of a mineral without actually seeing it in the soil. The disadvantage of this approach is that it cannot easily predict the rate at which minerals will dissolve. Theories that focus on microscale processes assume specific chemical reaction mechanisms occur at mineral surfaces and are more successful in predicting the rate of mineral dissolution due to changes in the composition of the surrounding soil solution.^[10] Unfortunately, microscale processes require information that can usually only be generated under laboratory conditions, which, at best, only approximate the actual weathering environment in the soil. A knowledge of both macroscale and microscale processes is important in understanding the solubility of minerals.^[8]

Macroscale Processes

Theories to describe mineral dissolution based on macroscale processes assume that the minerals, which may be present in a soil, are only sparingly soluble in the presence of water. In other words, only a tiny fraction of the mineral dissolves at any one time. The amount that dissolves is in proportion to the chemical formula for the mineral. Chemical analysis of the soil solution in contact with the soil minerals, therefore, should yield information about the type of minerals present. For example, the dissolution reaction for the secondary mineral gibbsite can be written as follows:

where the subscript (s) refers to the solid mineral, (aq) to the ion in solution, and (l) for water. The $\rightleftharpoons$ symbol reflects the

Fig. 1 Activity-ratio diagram for synthetic gibbsite, natural gibbsite, microcrystalline gibbsite, and amorphous aluminum hydroxide.

Source: K_{diss} values taken from Johnson, Driscoll, et al.^[11]

assumption that the solid gibbsite mineral is controlling the concentration of Al^{3+} ions in the soil solution. Thermodynamics predicts that if gibbsite is acting to control the composition of the soil solution, then the product of the concentrations of the dissolved ions in the soil solution is a constant (often referred to as the solubility product; K_{so}). The K_{so} of a mineral is in theory a unique quantity that is specific to the chemical composition and chemical structure of the mineral.^[9]

A visual representation of the ability to predict the presence of a mineral based on the concept of the K_{so} is shown in Fig. 1 for the mineral gibbsite, where the product of the concentrations of the dissolved ions in soil solution represented by Eq. 1 has been written in the form of a straight line as follows:

$$\log(\text{Al}^{3+}) = K' - 3\text{pH} \quad (2)$$

The term $\log(\text{Al}^{3+})$ represents the activity of Al^{3+} in solution (a measure of concentration), K' is a constant whose value is dependent on K_{so} , pH is the activity of H^+ in solution, and the number 3 represents the fact that it takes 3 H^+ ions to release one Al^{3+} ion. Experimental data points plotted on such graphs, which fall along the linear lines, are taken to indicate the presence of the mineral in the soil. If the data points fall in a region above the lines (region of supersaturation), conditions are favorable for the formation of the mineral (a precipitation reaction). If the data points fall in a region below the lines (region of undersaturation), conditions in the soil are considered too severe for the mineral to survive for long periods of time and unlikely that the mineral would be present in the soil.^[12] The four straight lines illustrate that solubility is not just dependent

on the chemical composition of a mineral, but also on its degree of crystallinity (amorphous is more soluble than synthetic) and size (microcrystalline is more soluble than more normal-sized particles).^[13]

The concept of the solubility product for minerals and the use of diagrams (often termed activity-ratio or activity-activity diagrams) as shown in Fig. 1 provide a useful means of predicting mineral behavior in soils, often by delineating boundaries for possible reactions between several minerals.^[13–15] The approach is dependent, however, on the assumption that the rate at which minerals dissolve is not limiting and thereby influencing the concentrations of ions in solution. Predicting rates of dissolution in specific soil environments is best viewed as a microscale process.

Microscale Processes

It is generally accepted that the rate of dissolution of minerals in soils is controlled by chemical reactions along mineral surfaces at distinct surface features that can include dislocations, etch pits, and micropores.^[16] The presence of surface features such as dislocations, etch pits, and micropores is taken as an indication of a population of surface reactive sites where dissolution reactions are favored above those possible along the total surface area of a mineral.^[8] The dissolution reaction at the surface reactive sites is considered as a two-step process. The first step involves the relatively rapid formation of a surface species as the result of the reaction with entities in soil solution such as H^+ , OH^- , H_2O molecules, and inorganic and organic ligands. The second step, and the one that is considered rate limiting, involves the transformation of the surface species into an activated complex with the eventual release of constituent ions to the bulk solution.^[7] Dissolution at the microscale, therefore, can be considered as a function of the reactive surface area of the mineral, the nature of the inherent chemical bonding structure that comprises the mineral, and the presence of various chemical species in the soil solution. Thus the dissolution rate of a mineral is not a fixed numerical quantity but dependent upon a number of variables which may change with time due to changes in the physical size of the mineral itself, as well as changes in the surrounding soil solution.^[8] It is possible to calculate approximate rates of dissolution for various classes of primary and secondary minerals, but local conditions within the soil should also be considered when predicting mineral solubility.

Abstract

Minirhizotron is a useful technique to study root system dynamics by means of a transparent tube and a root image acquisition device. It is non-destructive and less time-consuming; has high sensibility to detect fine roots (down to 0.09 mm diameter); and tracks the appearance, growth, and disappearance of individual roots over time. However, its use is limited to some soil types, and the measurements of root density in the top layer soil obtained using this technique are often found to be underestimations.

INTRODUCTION

Traditionally, root extraction methods have been used at the different crop growth stages to characterize the root system. These methods are based on the collection of unaltered soil samples with a probe of a known volume, separation of the soil from the roots by washing, and digitalization of the roots to measure their length and surface area per unit volume using a scanner and root analysis software. The root surface area can also be measured using leaf area meters. A more basic option consists of counting the roots in a cross-sectional plane of the sample. The manual extraction of the roots from soil samples is, without a doubt, the most exact method. However, its disadvantages are as follows: 1) it is a destructive technique; 2) there is no effective distinction between live and dead roots; 3) fine roots can be lost depending on the opening of the mesh used; 4) the almost transparent nature of many roots prevents the analyst from recovering them; 5) normally, samples are taken from only one crop growth stage (The study of root dynamics would require samples to be obtained during all growth stages.); and 6) it is a laborious technique and requires a significant amount of time *in situ* as well as in the laboratory.

Continuous non-destructive assessment of root growth has been practiced under field conditions for decades. This involves observation of root growth against glass or rigid plastic barriers. The oldest systems consisted of barriers as simple as a vertical glass pane buried in the soil with a big hole or trench alongside, so that an observer can see the roots growing against the glass. Rhizotron is another type of permanent system designed for examining the root

growth of a plant; it contains enclosed columns of soil with transparent plastic windows that permit viewing, measuring, and photographing. Owing to its smaller size, rhizotron can be used in replicated experiments. Great advances have been made in another non-destructive system for the study of roots called minirhizotron.

WHAT IS A MINIRHIZOTRON?

Minirhizotron is a transparent tube that is inserted into the soil permanently into which an image capturing system is introduced (camera, video system, or a portable cylindrical scanner) which is connected to a computer via an image capturing software, thus allowing the roots intercepted by the wall of the tube to be observed (Fig. 1). Subsequently in the laboratory, the images obtained are analyzed using a computer equipped with specific software to obtain the root parameters.

TUBE CHARACTERISTICS AND INSTALLATION

Normally, minirhizotron is cylindrical and rigid and can be made of different materials (Plexiglas, polycarbonate, glass, etc.). Tube type can affect the root growth pattern within a species.^[1] Although the cost of the minirhizotron equipment is quite high, the placement of multiple tubes allows the cost to be reduced as compared to rhizotrons. Minirhizotron tubes are sealed or covered to exclude moisture. Typically, the above-ground portion of the minirhizotron is completely opaque and painted white. The upper part of the tube is

Fig. 1 Diagrammatic representation of minirhizotron with cylindrical scanner as image acquisition device.

covered with an opaque cap. These precautions are taken to reduce thermal fluctuations within the tube and exclude light, which can affect rooting along the tube.

Minirhizotrons have been installed in forests, orchards, grasslands, deserts, agricultural systems, controlled environment chambers, and greenhouse lysimeters.^[2] The tube installation procedure is crucial to guarantee a correct measurement. When installing the minirhizotron tube, disturbances around it, such as soil compaction or air gaps between the tube and the soil that affect the root growth, creating conditions around the tube that are not the same as those found in the surrounding soil, need to be minimized. A common approach is to use an auger or a corer to excavate a hole with the same diameter as that of the minirhizotron tube to the desired depth. The minirhizotron tube is then inserted into the hole. Another method, namely, two-step tube installation, can also be used.^[3] First, a spiral-slip auger, with a diameter somewhat less than the tube diameter, is used to remove the majority of the soil. Then the hole is cut to its final diameter using a reverse taper bit. As a final step before tube insertion, a fine circular wire brush is used to remove soil striations that may have been incurred during the boring procedure.

The soil type will affect the tube installation method used. The abovementioned methods work well for medium textured (sandy loam) soils. Heavy textured soils, soils with abundant rocks and cobbles, soils with argillic horizons, or loose structureless soils are more problematic. The time of the year can also affect tube installation. Dry clay soils offer a great deal of resistance to coring, while wet clay soils can smear the outside surface of the minirhizotron tubes reducing visibility. When clay soils dry, they may develop cracks, which, on the one hand, separate the soil from the tube and, on the other hand, allow light to penetrate the soil.

The fixed tube of the minirhizotron can be inserted into the soil at angles ranging from 0° (horizontal) to 90° (perpendicular). Image acquisition device is calibrated according to this angle. The orientation of the tube at 0° allows many images to be obtained at the same depth, while slanted tubes provide greater information about the distribution of the roots throughout the profile and, at the same time, are simpler to install. The vertical placement of the tube can instill in the roots a tendency to grow downward lengthwise along the tube. The most commonly used angles are 30° and 45° with the vertical.

Once the tube has been placed, a waiting period must be allowed before proceeding to the capture of images. This period is called the return to equilibrium. After this time, the images are taken *in situ* with a predetermined frequency depending on the species studied.

IMAGE ACQUISITION DEVICE

The still camera, video camera, or cylindrical scanner is connected to an indexing handle that allows the system to move rapidly and accurately from one field of view to the next (depths) and provides a precise method for rapidly collecting images at the same location over a period of time.^[4] The existing tendency is for these devices to be connected to a laptop computer, which, being more easily organized, verifies whether the images were correctly taken and allows overlaying them in the field to ensure that the same locations were photographed. The laptop computers are specifically suitable for field work, as the high light intensity does not allow conventional computers to be used. The use of these devices requires the use of batteries, which can be problematic when a large number of images are to be taken. When working with a miniature video camera inside the tube, it is necessary to take into account that it requires a lighting source, and cameras have been fitted with incandescent or ultraviolet (UV) lights. The use of incandescent or UV light, however, generates heat within the tubes, which would be transferred to the adjacent soil. The heat generated by minirhizotron lighting systems may alter root growth and development more at depth than at the surface, especially when soil temperatures are lower.^[5]

Fig. 2 Root image acquired by a minirhizotron. (A) Original image and (B) image after being analyzed with a root image analysis software. Root length, diameter, area, and volume are measured using a series of straight length lines called segments as illustrated.

IMAGE ANALYSIS

Normally, image analysis is carried out completely in the laboratory, manually using one of the existing image analysis software packages (WinRHIZO Tron & Tron MF, ARCOS, etc.). The operator performs all aspects of the analysis by hand, i.e., opening and aligning the images through tracing root length and diameter in order to assign root condition codes (Fig. 2). When more than one person is involved in the analysis of the images, errors can occur in the measurements as observation capacity varies from one person to another. Automated techniques for minirhizotron image processing have increased the speed of root data collection, as well as the number and size of the experiments that can reasonably be analyzed with a single minirhizotron.^[6] These techniques are in an initial stage of development and must be improved. For the study of roots, color images provide better results than black-and-white images. However, black-and-white images require less memory capacity. Background homogeneity and color are major determinants of quality as well as the behavior of a minirhizotron toward light and the uniformity of lighting. The best fit has been found in clay soil, owing to the greater homogeneity of its background.

The direct measurements that can be obtained from the processing of images from the minirhizotron are root numbers, length, area, volume, and diameter. From these measurements, the root length density is calculated, and studies are performed on the production and turnover (mortality) of fine roots over time, thus obtaining their life span. In addition, the minirhizotron allows the determination of root distribution throughout the soil profile. Root biomass also can be calculated with the minirhizotron, which is estimated using a previous calibration with a manual soil core extraction method in the same soil and for the same species.

The most important question raised about the use of minirhizotrons is whether the estimations are comparable

to those made with soil core extraction methods. The results obtained in different studies have shown how in some cases there is a very good match. In others cases, an underestimation is observed, and on occasion, there is no correlation whatsoever (Fig. 3). The main problem in obtaining a good correlation is experienced in the top layer soil (0–10 cm). It is for this reason that the top layer data are at times not included, so as to obtain a correlation with regard to the rest of the depths (Fig. 3). The problem arises because the top layer of the soil is most disturbed when the tube is inserted

Fig. 3 Comparison of root length density (RLD) obtained by manual root extraction method and by minirhizotron for four crops (ns, not significant; s, significant).

Source: Adapted from Franco & Abrisqueta,^[3] Machado & Oliveira,^[7] and Heeraman & Juma.^[8]

and it is where the worst root contact exists with the tube, which is influenced by the type of soil and its water content.

CONCLUSION

Minirhizotron, in a right soil, offers an opportunity to take non-destructive root samples over different growth stages, with a low consumption of time and high sensibility to detect fine roots (down to 0.09 mm diameter). This device makes it possible to study the appearance, growth, and disappearance of individual roots over time. Its main disadvantage is that the results obtained are not in agreement with those from the manual extraction method if the top layer data are considered.^[7,9]

Mites

Hans Klompen

Museum of Biological Diversity, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Mites (Acari) form the most diverse lineage of Chelicerata. The basal division within Acari is between the orders, Parasitiformes and Acariformes. The former includes the Ixodida (ticks) and the Mesostigmata, a highly diverse lineage that is well-represented in soils. These mites tend to be relatively large, often with very discrete shields.

INTRODUCTION

Mites (Acari) form the most diverse lineage of Chelicerata. They are generally small (0.25–1 mm for most taxa) and are characterized morphologically by the division of their bodies. Functionally, there are two parts: one is the gnathosoma, containing the mouth, chelicera, and pedipalps and the other is the idiosoma, the body proper, containing the legs, eyes (if present), brain, and all remaining body systems. The nymphal and adult instars generally carry the four pairs of walking legs characteristic for Chelicerata, but the larval (and prelarval) instars carry only three pairs. An excellent review of mite morphology can be found in Evans.^[1]

The basal division within Acari is between the orders Parasitiformes (= Anactinotrichida) and Acariformes (= Actinotrichida). The former includes the Ixodida (ticks) and the Mesostigmata, a highly diverse lineage that is well-represented in soils. These mites tend to be relatively large, often with very discrete shields. Some Mesostigmata are fungal or pollen feeders but mostly retain the ancestral, predaceous lifestyle. In terms of their impact on soil ecosystems, a basic distinction between Uropodina (slow and often fungivorous) and Gamasina (active and mostly predaceous) is important.

The bulk of mite diversity is in the Acariformes, with at least four rather distinct taxa in soil environments: Astigmata, oribatid mites, “Endeostigmata,” and Prostigmata. Astigmata are often associated with ephemeral habitats. They have three nymphal instars, the second of which, the deutonymph, is highly modified for dispersal. It has no mouth, is well sclerotized, and generally carries an attachment organ (sucker plate) on the posterior venter. The other instars are often poorly sclerotized and can feed. The main group of interest for soil biologists are the oribatid mites. Like Astigmata, they are solid feeders, with generally well-developed chelate (biting) chelicera. However, oribatid mites are usually well sclerotized in the adults, can live for a long time (1–3 years of life cycles

are not unusual in temperate regions), have generally low reproductive rates, and disperse poorly.^[2] In contrast, Astigmata disperse very well, tend to have very high reproductive rates and live for much shorter periods of time.^[3]

The “Endeostigmata” form a paraphyletic assemblage of early derivative Acariformes. Poorly sclerotized and with diverse feeding behaviors, from fungivory to predation, these mites are particularly abundant in relatively poor quality habitats, including the deep soil. The final lineage of Acariformes is the Prostigmata sp. This group is enormously diverse in both morphology and life history. In studies of soil ecosystems, it tends to be ignored due to the difficulties in identifying these often very small and poorly sclerotized mites. Yet identification to at least major groups is desirable, as the main lineages, Anystina (including Parasitengona), Eupodina, Raphignathae, and Heterostigmae, are quite different in morphology, life history, and (most probably) ecosystem function. All of these mites are fluid feeders, with chelicera modified as stylets. Prostigmata include many fungivorous and predaceous taxa and a few true plant feeders.

Comprehensive keys to the species of soil inhabiting mites have been published for the former Soviet Union.^[4] Keys to the families (“Endeostigmata,” Prostigmata, oribatid mites) and genera (Mesostigmata, Astigmata) for North America can be found by Dindal.^[5] Comprehensive keys for soil mites in tropical areas are not yet available.

DISTRIBUTION AND ABUNDANCE

Mites are the most abundant group of arthropods within most soil and litter habitats, including deserts and arctic areas. Numbers of 10,000–500,000/m² are normal in temperate and tropical sites.^[6] Mesostigmata usually form about 20% of the total mite fauna (3000–4000/m²),^[6] with abundance and diversity generally being higher in forests

than in more open habitats. In temperate regions, the number of Uropodina is generally lower than that of Gamasina, but in the tropics Uropodina abundance can rival that of oribatid mites. Overall, Uropodina is strongly associated with soils of high organic matter content.

Astigmata have often been ignored in studies on soil fauna but can be common in disturbed sites, such as soil around isolated city streets, and cultivated fields.^[3,5] A similar association with disturbance is found for most Heterostigmae (Prostigmata). The contrast with oribatid mites is once again strong. Oribatid mites are generally very common in relatively stable habitats (10,000–300,000/m²)^[6] and usually form the bulk of mite biomass in forest ecosystems. However, many oribatid mites are quite sensitive to soil disturbance, and the fauna of conventionally tilled agricultural fields is generally depauperate. Unlike most other groups of mites, they cannot take advantage of the resource flushes that are characteristic of many agricultural practices (e.g., manure applications). Overall, the group is highly diverse, and most of the 150+ families described do occur in soil and litter habitats.

The “Endeostigmata” are not very diverse, although many species have a broad geographic range. Among the 126+ described families of Prostigmata, about 50 occur mostly in soil environments, but representatives of many other families may be encountered during sampling.^[7] The number of Prostigmatid and Endeostigmatid mites (these groups are often combined) varies dramatically by general habitat. Numbers vary from 7500/m² in moss turf banks in Antarctica to over 100,000/m² in pine forests in Northern Europe.^[7] Prostigmata plus Endeostigmata may form 40–50% of the total number of mites in deserts and grassland ecosystems, but this proportion drops sharply in temperate forests (less than 10%). The relative proportion of Prostigmata (+ Endeostigmata) to oribatid mites is occasionally reported, but this number may not be very informative. The different lineages in Prostigmata are sufficiently diverse; to lump them together into a single value may not be useful.

FUNCTION

The role of mites in soil ecosystems is only partially understood. It is clear that their role in overall energy flow is limited,^[6] and most research is concentrating more on indirect effects. These include fragmentation of litter (comminution) and soil formation, nutrient cycling, dispersal of microbial spores, and stimulation of the microflora (bacteria and fungi) by grazing. A second level of indirect regulation results from predation on both other microarthropods and nematodes. It is useful to distinguish the two: the first group of processes mostly impact the fungal decomposition pathway (few

mites feed directly on bacteria), while the second influences both the fungal and bacterial pathways.^[8] Most importantly from the standpoint of soil ecosystems, different groups of mites have distinctly different functions, and broad generalizations are nearly always obscuring, rather than illuminating.^[9]

Comminution, the breaking up of larger organic units such as dead leaves and wood into smaller pieces, is a process that is largely limited to oribatid mites and Astigmata. The other lineages are either predaceous, or feed by puncturing, not breaking up, fungal hyphae etc. Comminution greatly increases the surface areas on which bacteria can complete the actual process of decomposition. Through their feeding and production of fecal pellets, oribatid mites can alter the structure of the soil. As such, they are considered as the most important group of arachnids from the standpoint of direct or indirect effects on the formation and maintenance of soil structure.^[2,8] Many oribatid mites also sequester calcium and other minerals in their cuticle and thus their bodies may form important “sinks” for nutrients in some nutrient limited environments.

Oribatid soil mites disperse bacteria and fungi, both externally, on their body surface, and internally, by excreting undigested spores. Through this process they can enhance endomycorrhizal colonization.^[10] Such dispersal may be especially important in the early stages of saprophytic succession.^[11] Mites grazing on fungi influences both the composition and productivity of the microflora.^[11] What is poorly understood are the effects of these actions on decomposition rates.^[8,11] Compensatory growth of fungi in response to periodic grazing by mites and Collembola appears to be very important in the field and may significantly increase decomposition rates.^[11] In addition, comminution of litter and the disturbance of fungi by mite feeding may favor bacterial over fungal growth.

Mites are among the most important predators in the soil ecosystem, attacking most other components of the mesofauna. The two main taxa involved in this process are gamasine Mesostigmata and Prostigmata, but nematode feeding can be found in all taxa discussed.^[3] Strict specificity for microarthropods (most common among Prostigmata) or nematodes (some “Endeostigmata” and Mesostigmata) occurs, but the majority of mites are generalist predators, feeding on a variety of prey. So far, relatively little is known about the effect of arthropod predation in soil communities. In laboratory experiments (microcosms), predatory mites can suppress nematode numbers,^[12] but these results have not been translated to more realistic field conditions. In a broader sense, predation may alleviate grazing pressure by nematodes and oribatid mites on the primary decomposers, fungi and bacteria. Excessive grazing decreases, rather than increases, soil respiration and decomposition rates.

Modern Civilization and Soils

Kenneth R. Olson

*Department of Natural Resources and Environmental Sciences,
University of Illinois at Urbana-Champaign, Urbana, Illinois, U.S.A.*

Abstract

Contemporary use of soils is not greatly different from ancient use of soils. Many millions of hectares in the modern urban landscape have been altered or destroyed for construction of buildings, transportation, or mineral extractions. The archeological record shows that some ancient people abused their soils and that their civilizations were disrupted by the ecological and environmental consequences. One of history's greatest problems has been the cultivation and erosion of sloping lands. Repeated productivity losses on these soils would result in long-term costs to society, because this natural resource (capital) would eventually be depleted. Sustaining the long-term productivity and quality of all soil resources needs to be a national priority, which is essential to our nation's prosperity. It is in the national interest that management strategies and techniques continue to be developed to monitor and sustain soil productivity and quality.

INTRODUCTION

In many parts of the world, contemporary use of soils is not greatly different from ancient use of soils.^[1] The archeological record shows that some ancient people abused their soils and that their civilizations were disrupted by the ecological and environmental consequences. Some ancient populations, such as the Middle Mississippian culture near Cahokia, Illinois, were larger in population in 1200 A.D. than their modern descendants.^[2] The archeological record gives us reasons to ponder, whether contemporary societies are using their resources wisely.^[1] People should seek explanations for ancient population declines and shifts so they might avoid similar fates, because an important factor in the continuing prosperity of a nation is the nature of the husbandry of the soil and land resources through centuries of use and occupation.

The Middle Mississippian Indians settled in an area near Cahokia, in southwestern Illinois (adjacent to the current city of St. Louis, Missouri) in approximately 500 A.D.^[3–5] By 1350 A.D., the site was abandoned after peaking in the Lohmann phase (1050–1100 A.D.) and the Stirling phase (1100–1200 A.D.).^[2,5–7] During the later years of settlement, the population grew to 20,000 people, making it the largest city in the United States until the European settlement of Philadelphia and Pennsylvania exceeded 20,000 people in 1830. The Middle Mississippian people settled on the stream and lacustrine deposits in the American Bottoms of the Mississippi River valley. Previously, it would not have been possible to feed such a large population by hunting and fishing alone. The Middle Mississippian Indians

supplemented their diet by cultivating maize (corn) and garden crops on the silty soils (Fluvaquents) on floodplains.^[8] They could then store sufficient food for the winter season to feed the entire population. The people also cut down the adjacent forests for firewood and making structures and fences. This deforestation caused accelerated erosion of the steep, silty soils (Hapludalfs) on nearby hillsides. As a result, wood had to be transported to greater and greater distances over time. These Middle Mississippian Indians were also earthen mound builders. They created thousands of earthen burial and ceremonial (platform) mounds. The earthen mounds were built on clayey soils (Fluvaquents). They dug out the silty, clayey, and sandy stream deposits from the Mississippi River valley and carried the soil materials on their backs in sacks to the top of the mounds.^[2] Later, the original borrow areas were filled to build a large plaza by digging and transporting more soil materials in sacks from borrow areas farther away.

Some of these mounds (almost 800 years old) exist. The largest mound is called Monks Mound, which is 30 m high with a rectangular base of approximately 320 m × 294 m. War, fire, food shortages, and disease were the most likely causes for the collapse of the Middle Mississippian civilization, but the final causes for the collapse are the subject of considerable debate. It is difficult to understand how the wastes from 20,000 people could be disposed off without polluting the adjacent water and land. Waste disposal problems could have contributed to the contamination of the water supplies, especially the water in the borrow areas. Over time, the demand for maize without crop rotation and nutrient additions could have resulted in soil depletion and

reduced crop yields, which could have contributed to food shortages. Deforestation of forests, overgrazing of pastures and ranges, and overplowing of fields may have accelerated erosion in many ancient civilizations. Accelerated soil erosion may have diminished the ability of many farmers worldwide to produce satisfactory yields and maintain a reasonable standard of living.^[9] Tillage utilized in agriculture often accelerates soil loss from water and wind erosion.^[10] For survival and well-being, governments throughout the world need to respond to the challenges of the stabilizing erodible soils.

MODERN CIVILIZATIONS

World demand for food climbs higher each year as a result of both population growth and rising expectations. As a nation’s standard of living increases, diets often contain more of meat. This change may entail growing of feed crops, such as corn and soybeans, which lead to more erosion than of small grains and forage.^[11] In the Third World, farmers are being pushed onto steeply sloping, erodible lands that are rapidly losing their topsoil. Even in the American Midwest, many farmers have abandoned more biologically diverse and soil-conserving rotations that include forage and small grains (oats and wheat) in favor of continuous corn, or a corn and soybean rotation. In other parts of the world, farming has extended into semiarid regions where land is vulnerable to soil loss from wind erosion when plowed.^[12]

The loss of topsoil affects the ability of soil to grow food crops, by decreasing the availability of nutrients. This results in degrading the soil’s physical condition by increasing the need for fertilizers and irrigation, which, in turn, increases the cost of production. The loss of topsoil is a quiet crisis in the world economy, because unlike natural disasters such as earthquakes or volcanic

eruptions, it is largely a human-made crisis that unfolds gradually.^[11]

Soil degradation is more severe in sub-Saharan Africa than other tropics.^[12] This is where soil degradation has severely reduced the soil’s potential capacity to produce food, feed, and fiber. This is a result of physical, biological, and chemical deterioration due to erosion, desertification, laterization (formation of a stone-like layer high in iron), salt accumulation, excessive leaching and acidification, and nutrient imbalance.

Prior to the European settlement, many north-central U.S. soils were developed under prairie grass on nearly level plains and under forests on rolling hillslopes. European settlement and agricultural technology had significant impacts on north-central U.S. soils [Table 1](#).

During the Dust Bowl of the 1930s, severe droughts in the Great Plains of the United States resulted in crop failures and major dust storms. In 1935, with dust settling in the congressional offices in Washington, District of Columbia, the Congress passed a law, creating the Soil Conservation Service to address the erosion problem. At that time, soil erosion of row cropland became so severe, and farm debt became so high, that lands were abandoned in many states such as Illinois, Indiana, Kentucky, Tennessee, Oklahoma, and Missouri. Numerous research stations and demonstration farms were established in the north-central United States to test and disseminate information on how to restore soils and improve crop yields and farm income on hilly, highly eroded soils. Management techniques that helped achieve these goals included the removal, crushing, and application of limestone from nearby hills to highly eroded soils with acidic subsoils. Rock phosphate was added to the phosphorus-poor soils and forage crops were seeded as pasture for beef and sheep, reducing the need for a yearly tillage. Gullies were filled on the steep hillslopes as well.

In the 1950s, nitrogen fertilizer became available at low cost and the increasing acreage planted with soybeans

Table 1 Agricultural technology impacts of European settlement on north-central United States.

Timeline	Agricultural technology events related to European settlement
1814	The introduction of the cast iron plow made it possible to plow the forest land but not the wet, sticky prairie soils. Consequently, settlement in the early 1800s along the Ohio, Mississippi, and Missouri Rivers resulted in the clearing of forest and cultivation of sloping land which was easily eroded
1837	The John Deere Company started mass producing a steel plow which could be used to plow the prairie lands. Shortly thereafter, some of the agriculture from the highly eroded forest soils shifted or moved to the prairie soils
1850s	The steam engine was introduced which helped with the wheat harvest and increased wheat production. In 1879 the U.S. Drainage Act and Levee Act allowed the drainage (initially surface ditches and later tile systems) and farming of swampy prairie areas in states like Illinois
1890–1950	Gasoline tractors replaced horses resulting in a decline in the acreages of oats and hay
1920s	Agronomic research resulted in better oil seed varieties of soybean. Crop rotations which had previously included corn planted in rows approximately 1 m wide, drilled wheat and oats in very narrow rows approximately 7.5 cm wide, and perennial hay was replaced by an intensive rotation of corn and soybeans. Over time, the soybeans were grown in wide rows for grain instead of being closely grown for forage; consequently, accelerated soil erosion occurred

and corn increased erosion. In the 1960s, the moldboard plow was partially replaced with a chisel plow, which reduced soil loss by leaving plant residue on the surface (conservation or mulch tillage). In the 1970s, no-till planting of limited acreages of corn and soybean further reduced tillage and soil erosion, but often with increased use of herbicides. In the 1980s, ridge tillage, which left residues between the rows at planting, to reduce erosion, became more popular. Row cultivation was used to control weeds between the rows and to maintain ridges.

The U.S. Food Security Act of 1985 resulted in millions of hectares of highly erodible lands being put into forages or trees for 10 years or more, which further helped reduce soil movement from the row cropland. Many states developed conservation programs in the 1980s that required soil loss to be reduced over a specific time, to the tolerable soil loss level, ranging from 2 to 11 metric tons per hectare per year.

EFFECTS OF AGRICULTURE ON SOILS

Sheet and rill erosion rates on cropland have been declining in United States.^[13] Under the production of agricultural systems, however, 23% of U.S. cropland is eroding at rates higher than that of the tolerable soil loss.^[14,15] The effects of erosion on cropland soils depend, in part, on the characteristics of the soils, and the landscapes in which they occur. Even under favorable climatic conditions, topography, and parent materials, soil formation is a slow process, requiring hundreds of years to develop topsoils and subsoils. Adopted conservation management improvements, advances in conservation tillage technology, and land use changes have contributed to sheet and rill erosion-rate reductions; however, there can be a net soil loss and reduced long-term soil productivity even under no-till systems. When considered in the context of long-term productivity, erosion rates alone are not the only indicator of soil degradation. Degradation of soil structure and aggregation or loss of irreplaceable soil attributes are much more serious in certain soils than others when compared at the same erosion rates. Documented on-farm and off-site damages include loss of soil, sedimentation in streams, reservoirs, and fields, loss of nutrients, soil property changes, soil productivity losses, and air, soil, and water pollution.

Government programs either provide incentives or require soil loss to be held within tolerable levels. On average, the total soil loss resulting from wind and water activity has been declining, in part, as a consequence of government programs. However, erosion and sediment deposition are locally and regionally significant and, thus, perceived by the scientific and non-scientific communities as a serious threat to our economy and environment.

EFFECTS OF MODERN URBANIZATION AND INDUSTRIALIZATION ON SOILS

For the past 200 years, as European settlement increased in the United States, the disturbance and alteration of the soils have accelerated. Many millions of hectares in the urban landscape have been altered or destroyed for constructing buildings, transportation, or mineral extractions. Vast areas of soils near urban centers have been excavated or disturbed for the construction of buildings, roads, railroads, cemeteries, canals, utility lines, and landfills. In addition, there has been surface and subsurface mining for various minerals, including coal, limestone, clay, sand, and gravel apart from waste disposal. Topsoils and even subsoils are often removed and sold from constructions sites. Topsoil has become a commodity that is of value and is often transported and sold to the highest bidder. In the urban landscapes, soils (often both topsoil and subsoil) have been removed, exposing the dense parent materials, which are often built on and then landscaped using a thin layer of sod. This sod has difficulty in growing roots into the dense parent material. Often, soils are no longer present and cannot accept or hold the rainwater on the landscape. Runoff is much greater than it was prior to the alteration. The lack of soil water storage and covering of other soils in the landscape by roofs, sidewalks, driveways, and roads has resulted in more runoff and increased flooding. As humankind have tried to clean up the air and water, the industrial and urban pollutants, urban and industrial wastes, and sewage sludges have either been consolidated or buried under the soil materials, or transported and spread on soils as amendments. Fortunately, environmental regulations no longer allow urban and industrial wastes and sewage sludges to be transferred to the air, rivers, lakes, or oceans.

CONCLUSION

Contemporary use of soils is not greatly different from ancient use of soils. Many millions of hectares in the modern urban landscape have been altered or destroyed for construction of buildings, transportation, or mineral extractions. The archeological record shows that some ancient people abused their soils and that their civilizations were disrupted by the ecological and environmental consequences. One of history's greatest problems has been the cultivation in and erosion of sloping lands. Repeated productivity losses on these soils would result in long-term costs to society, because this natural resource (capital) would eventually be depleted. Sustaining the long-term productivity and quality of all soil resources needs to be a national priority, which is essential to our nation's prosperity. It is in the national interest that management strategies and techniques continue to be developed to monitor and sustain soil productivity and quality.

Mulch Farming

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Mulch farming maintains or enhances soil quality by conserving soil and water resources, improving soil organic carbon content, increasing soil biodiversity, strengthening nutrient cycling mechanisms, and regulating soil temperature regime. Mulch farming increases the probability of achieving agricultural sustainability through: 1) increasing production; 2) decreasing costs of fertilizers and water inputs; and 3) preserving the resource base and its productive potential.

INTRODUCTION

Mulching, the practice of leaving crop residues and other biomass on the soil surface to protect it from climatic elements, is an ancient practice. Its application, however, is even more relevant than ever before because of the serious global issues relevant to human population growth, scarcity of prime agricultural land, ecological benefits of nutrient recycling and optimizing rates of fertilizer input, severe problems of soil degradation, adverse water quality, and the accelerated greenhouse effect. It is an ecological approach to addressing the problem of sustainability, soil degradation environment quality, and nutrient cycling. Conventional agricultural practices, based on clean cultivation and intensive use of inorganic fertilizers and chemical amendments, make soils susceptible to degradative processes, e.g., erosion, acidification, and emission of greenhouse gases to the atmosphere. Stabilizing the atmospheric concentration of greenhouse gases is a major global challenge.^[1] The global release of soil organic carbon (SOC) from agriculture is estimated at 800 Tg C/yr (T = tera = 10^{12} = 1 million metric ton).^[2] Soil restoration (for enhancement of SOC content) is an important and feasible option for mitigating the greenhouse effect^[3–5] and enhancing soil quality for increasing production and improving the environment.^[6,7] These desirable properties and processes are achievable through frequent applications of crop residue mulch and other mulch farming techniques.

MULCH TYPES

Mulch is any material, other than soil, specifically established at the soil–air interface to manage soil and water and create favorable environments for plant growth. Most mulches are organic materials of plant origin comprising crop residues, weed biomass, leaf litter, and by-products of agroindustries, e.g., saw dust, rice husk, and corn cobs.

However, there is a wide variety of mulch materials ranging from gravels and plastic to crop residues and planted fallows. Mulches can be broadly classified into two categories: organic and inorganic mulches (Fig. 1).

1. *Organic mulches.* Most mulch materials used in agriculture are of organic origin and comprise crop residue used both *ex situ* and *in situ*.
2. *Inorganic mulches.* Three most common inorganic mulches are plastic, gravels, and water.

MULCH PROCUREMENT FOR ARABLE LAND

Crop Residues

The most common practice of mulch procurement for use on agricultural land is the use of crop residues from the previous season's crops. Crop residue is a renewable resource, and annually a large quantity of residues are produced in the world.^[9,10] Residues produced in the world during 2001 were estimated at 3758 million Mg, of which 2802 million Mg (75%) were from cereals, 305 million Mg (8%) from legumes, and 651 million Mg (17%) from other crops (Table 1). The amount of residue produced by seven crops in the tropics is estimated at 1838 million Mg (Table 2). Properly used as mulch, these residues can cover the entire arable land of 1500 million hectares at an average rate of 2.53 Mg/ha. Therefore, crop residues are an important resource that need to be carefully and judiciously used for sustainable use of soil, water, and other natural resources.

Crop residues management

Management of crop residues is an important strategy of mulch procurement. Crop/plant residues, produced by annuals or perennials, *in situ* or *ex situ*, used as mulch can improve soil quality, increase productivity and sustainability,

Fig. 1 Different types of mulch materials.
Source: From Larson.^[8]

and enhance environmental quality (Fig. 2). Principal management alternatives outlined in Fig. 3 indicate four options, namely: 1) mulching, 2) using as animal feed, 3) composting, and 4) burning. Using residues as mulch is the best option for controlling soil erosion, conserving soil water, and at the same time replenishing plant nutrient reserves.

Planted Fallows and Cover Crops

Cover crops, legumes, or grasses generally grown to produce biomass and provide ground cover are a good source of mulch. Suitable cover crops are those that: 1) establish rapid ground cover; 2) improve soil fertility through biological nitrogen (N) fixation and recycling nutrients;

Table 1 Estimates of crop residues produced by cereals, legumes, and other crops.

Crops	Residues produced (106 ton/yr)	
	1991	2001
Cereals	2563	2802
Legumes	238	305
Oil crops	162	108
Sugar crops	340	373
Tubers	145	170
Total	3448	3758

3) suppress weeds and other pests; and 4) produce a large quantity of biomass that can be used as mulch. Selected legumes and grasses, appropriate for the soil and environment, can ameliorate soil properties and produce the mulch material in a short time interval.^[12] Deep rooted cover crops are also effective in improving subsoil properties.

BENEFITS OF MULCH FARMING

Mulch farming is an ecological approach to agriculture. Properly used, it can improve and sustain agricultural

Fig. 2 Interactive effects of mulch farming on soil quality/agronomic productivity, water quality, and greenhouse effect.

production, enhance soil quality, and have minimal adverse effects on the environment (Fig. 4). Principal benefits of mulch farming are briefly described in this figure.

Soil-Surface Management and Erosion Control

Soil erosion by water and wind is the principal degradative process,^[13] and it adversely affects soil quality.^[14,15] Mulching, at the rate of 4–6 Mg/ha, is an effective erosion-control measure.^[16] Larson^[8] recommended the use of crop residue mulch for erosion control in the Mid-western United States. Moldenhauer and Wischmeier^[17] observed significant reduction in soil erosion by mulch farming practices. Both runoff and soil erosion decrease

exponentially with an increase in surface area covered by mulch (Fig. 5). Structural improvement by mulching is due to an increase in SOC or humus content that facilitates the formation of organomineral complexes and an increase in soil biodiversity, notably the activity of earthworms, termites, and other beneficial soil fauna.^[18]

Water Management

There are four types of water, namely: 1) surface water; 2) ground water; 3) soil water; and 4) rainwater. Mulching affects all four types of water, but has a major impact on soil water and surface water. Mulching decreases runoff by improving infiltration rate, replenishes soil water by

Fig. 3 Methods of procurement of mulch materials.

Fig. 4 Economic, ecologic, and natural resource improvements by mulch farming.

improving retention pores, and recharges groundwater by increasing percolation. Partitioning of rainwater into runoff, soil water, and groundwater components is influenced by mulching through its effect on the water balance. Mulching increases soil water and groundwater components by decreasing runoff and soil evaporation. Mulching improves soil water storage and minimizes the risks of drought. When the soil is wet at about field capacity level, as is the case soon after rainfall or irrigation, mulching decreases the evaporation rate and prolongs the duration during which soil remains moist (Fig. 6).

Fig. 5 A schematic depicting an exponential decline erosion with increasing soil cover by mulching.

Soil Temperature Management

Crop residue mulch has a buffering or moderating effect on soil temperature regime. It influences the extremes by decreasing the maximum soil temperature and increasing the minimum soil temperature. Therefore, soil temperature range is narrower in mulched than in unmulched soil. Mulching increases soil temperature in the morning and decreases it in the afternoon (Fig. 7). Plastic mulches are often used to increase soil temperature in horticultural and other high-value plants. Soil temperature effects of mulching are due to both direct and indirect effects. Direct effects are due to reduction in insolation or energy load on the soil surface. Mulching shades the soil and prevents the

radiation reaching the soil surface. Indirectly, mulching influences soil temperature through its effect on soil's heat capacity and thermal conductivity.

Nutrient Cycling and Soil Fertility Enhancement

Severe nutrient depletion in sub-Saharan Africa^[19,20] and elsewhere can be controlled through nutrient cycling. Depending on plant species and management systems, crop residues contain a considerable amount of plant nutrients. Total amount of plant nutrients in crop residues range from 40 to 100 kg/Mg of residues.^[9] On a global scale, crop residues contain 22.6 million Mg N, 3.6 million Mg phosphorus (P), 47.4 million Mg potassium (K; [Table 3](#)). Estimates of global fertilizer consumption show annual use of 113 million tons of NPK vs. 74 million Mg contained in crop residues. In comparison, annual fertilizer consumption is 16 million Mg of NPK in the United States vis-à-vis 9 million Mg contained in crop residues. Estimates of N, P, and K contained in crop residue in the world and in the developing countries are shown in [Tables 4, 5, and 6](#), respectively. Thus, cycling of nutrients contained in the

residue is an important factor affecting soil quality and agronomic yields. It is feasible, therefore, that a considerable quantity of fertilizer can be saved by returning crop residues to the soil. Indeed, mulching and residues management are effective nutrient recycling mechanisms.

Soil Biodiversity

Applications of crop residues mulch improve the activity of soil micro- and macrofauna and biomass carbon (C). The relative magnitude of biomass carbon is a good indicator of soil quality. Mulching improves population and activity of soil fauna especially those of earthworms and termites. These organisms improve soil structure by burrowing, mixing and soil turnover activities. They decompose and mineralize crop residues and make nutrients available to plants.

The Greenhouse Effect

The atmospheric carbon dioxide (CO₂) concentration has increased by approximately 30% from 280 ppm in 1850 to approximately 370 ppm in 2000.^[21,22] This increase is attributed to two principal human activities: 1) land use change and soil management (1.6 Pg C/yr; 1 Pg = petagram = 10¹⁵ g) and 2) fossil fuel consumption (6.8 Pg C/yr).

The rate of increase of atmospheric CO₂ concentration is approximately 1.5 ppm or 3.5 Pg C/yr. Total crop residues production in the world estimated at 3460 million tons per annum^[9] contains 1.5 Pg of C. This is approximately 43% of the annual atmospheric increase of 3.5 Pg/C and cannot be ignored in the context of global C cycle. This C can have a major effect even if only 10% of the 1.5 Pg can be sequestered in soils as humus. In addition to the direct effect,

mulching also sequesters C through erosion control and increase in biomass production.^[23]

MULCHING AND AGRICULTURAL SUSTAINABILITY

Mulch farming affects agricultural sustainability through its impact on soil quality and productivity (Fig. 8). Mulch-induced changes in soil quality set in motion restorative processes leading to soil and water conservation, nutrient cycling and soil fertility improvement, improvement in soil structure and C sequestration, increase in soil biodiversity, and soil structure enhancement. Mulch farming improves energy use efficiency by 1) reducing fertilizer use through decreasing nutrient losses in runoff and erosion and recycling plant nutrients; 2) decreasing irrigation needs through increasing infiltration and reducing losses due to runoff and evaporation; 3) decreasing herbicide use through suppressing weed growth; and 4) decreasing fuel consumption through reduction of tillage operations and vehicular traffic.

Crop residues are also a renewable source of energy that can be used in the farm household. Energy content of straw, depending on crop species and other factors, ranges from 3000 to 4000 kcal/kg.^[24] Energy value of 1 Mg of residues may be as much as 9 million BTU, 18.6×10^9 J, or equivalent to two barrels of oil.^[25] Estimates of fuel energy in crop residues show that cereal straw produced annually in the world is equivalent to 47×10^{18} J of energy (Table 7).^[10] However, traditional use of biomass (crop residue, cattle dung, etc.) can have severe adverse impacts on the environment (Fig. 9).^[26]

LIMITATION OF MULCH FARMING

Biomass, the principal mulch material, has numerous alternative uses especially for resource-poor farmers of the tropics. Crop residues are used for feeding livestock for building fences and homesteads and as fuel for cooking and household energy use. It is a precious commodity, and little if any is left behind on the field as mulch on small farms in the developing countries. Under some circumstances, mulches may also have negative effects on crop growth due to cool soil temperature during spring in temperate regions, high incidence of pests and pathogens, and N immobilization.

Fig. 8 Mulch farming and agricultural sustainability.

Fig. 9 Biomass burning as household fuel and the environment.

CONCLUSION

Mulch farming maintains or enhances soil quality by conserving soil and water resources, improving SOC content, increasing soil biodiversity, strengthening nutrient cycling mechanisms, and regulating soil temperature regime. Mulch farming increases probability of achieving agricultural sustainability through: 1) increasing production; 2) decreasing costs of fertilizers and water inputs; and 3) preserving the resource base and its productive potential.

Mulch farming has a potential to improve environmental quality by: 1) decreasing soil erosion and transport of chemicals in runoff, mulch farming decreases risks of eutrophication of surface waters and contamination of groundwater; and 2) reducing emission of radioactively active gases from soil to the atmosphere through increasing SOC content, stabilizing C within aggregates as organomineral complexes, decreasing losses due to soil erosion, and improving biomass production.

Mycorrhiza of Forest Ecosystems

Ian A. Dickie

School of Forest Resources, University of Minnesota, St. Paul, Minnesota, U.S.A.

Abstract

Mycorrhiza are involved in every aspect of forest soil ecology—they are central to plant nutrient uptake, they can short-circuit the nitrogen cycle, they participate in primary weathering of soil nutrients, and they provide a major input of carbon into the soil ecosystem. In addition, a lack of mycorrhizal fungi may limit the ability of forest tree species to establish slowing forest succession on disturbed sites. At least a basic understanding of mycorrhiza is therefore critical to understanding both soil and plant ecology.

INTRODUCTION

Most land plants (>80% of angiosperms and almost all gymnosperms) form mycorrhiza: symbiotic associations between plant roots and fungi that increase plant nutrient uptake.^[1,2] Mycorrhizal fungi are an important component of the soil ecosystem, with ca. 200 m of mycorrhizal hyphae per gram of forest soil.^[1] Several types of mycorrhiza occur, including arbuscular mycorrhiza (dominants of grasslands, many tropical, and some temperate forests), ectomycorrhiza (dominants of boreal, most temperate, and some tropical forests), and ericoid mycorrhiza (common in temperate and boreal forests and heathlands). Mycorrhiza plays a critical role in plant nutrient uptake, particularly of phosphorus (P), NH_4^+ , and organic nutrients. In return for increased nutrient acquisition, plants direct 10–30% of total fixed carbon (C) to supporting mycorrhizas. This represents an important flow of C to the soil ecosystem, creating “mycorrhizosphere” communities in association with fungal hyphae.

MYCORRHIZAL TYPES

Arbuscular mycorrhizas are the ancestral state of all land plants, and approximately 67% of all angiosperms and nearly all non-Pinaceae gymnosperms retain this association.^[2] Arbuscular mycorrhizas are formed by most tropical and many temperate forest trees, as well as many forest understory plants. Arbuscular mycorrhizas are characterized by the internal colonization of root, with the fungus forming characteristic structures (arbuscules) within the root cells. Arbuscular mycorrhizas are formed by fungi in the order Glomales.

While less common than arbuscular mycorrhiza, ectomycorrhizas are particularly important in forest ecosystems (Fig. 1). Predominately ectomycorrhizal plant families include the Pinaceae, Fagaceae, Myrtaceae, Dipterocarpaceae, Salicaceae, Betulaceae, and the leguminous

subfamily Caesalpinioideae, among others.^[1] Although these species account for only around 3% of plant diversity, they include the dominants of most temperate and boreal forests and some tropical forests. In ectomycorrhiza, the fungus forms a mantle, which envelops root tips, and a Hartig net, which penetrates between the cells of the epidermis and cortex of the root but does not penetrate cells. The fungi forming ectomycorrhizas are primarily Basidiomycetes, as well as some Ascomycetes and some species of the Zygomycete genus *Endogone*. Many fungi forming ectomycorrhizas produce conspicuous sporocarps, some of which are economically important edibles (e.g., chanterelles, truffles, cepes, and matsutake).

Ericoid mycorrhizas are exclusively formed by plants in the Ericales (Ericaceae, Epacridaceae, and Empetraceae). These plants are an important component of high altitude, temperate, and boreal forests and heathland ecosystems. Ericoid mycorrhizas form a loose weft of undifferentiated hyphae on the root surface, with extensive intercellular structures within root cells. Fungi forming ericoid mycorrhizas are primarily Ascomycetes, and some are Basidiomycetes.^[3]

In general terms, arbuscular mycorrhizal forests tend to dominate low-latitude and low-elevation sites with P-limited soils. Ectomycorrhizal forests become dominant with increasing latitude and elevation and on more acidic and nitrogen (N)-limited soils. Ericoid mycorrhizas dominate at the highest elevations and latitudes and on highly acid or organic soils.^[1] Other forms of mycorrhiza also occur in forest ecosystems, including ectendomycorrhizas, arbutoid, orchid, and monotropoid mycorrhizas.^[1] None of these types dominate forest ecosystems.

NUTRIENT UPTAKE

Mycorrhizas can considerably increase plant nutrient uptake, and for many plants, they are the primary mechanism for nutrient uptake. All forms of mycorrhiza greatly

Fig. 1 Ectomycorrhiza formed by the fungus *Cortinarius* sp. on the roots of a potted oak seedling. Single triangles indicate ectomycorrhizal root tips, and double triangles indicate fungal rhizomorphs.

increase the ability of plants to explore the soil. Estimates of the length of mycorrhizal hyphae in forest ecosystems range from 300 m to 8000 m of fungal hyphae per meter root length.^[4] By increasing effective root surface area, mycorrhizal fungi can substantially increase nutrient uptake, particularly of nutrients such as P and NH_4^+ that have low mobility in soils. The small size of fungal hyphae (down to $<2 \mu\text{m}$ diameter) also permits fungal hyphae to explore soil pore spaces that are inaccessible to roots.

While all mycorrhizas increase the root surface area, ectomycorrhiza and ericoid mycorrhiza are also capable of obtaining nutrients from sources which are otherwise unavailable to plants. Ectomycorrhiza and ericoid mycorrhiza are capable of obtaining N and P from organic sources, even where those organic nutrients are protected by structural components of litter.^[1] This has the potential to short-circuit the N cycle, with plants obtaining N directly from organic sources without that N first being mineralized. Ectomycorrhiza may also increase the uptake of P, calcium, potassium, and magnesium through direct weathering of mineral nutrient sources.^[5] In addition to nutritional benefits, ectomycorrhizal fungi can increase plant tolerance of drought and heavy metal toxicity and increase resistance to disease.^[1]

C COSTS

The fungi involved in mycorrhiza are dependent on plants for C. Available estimates indicate that forest trees may transfer 10–30% of total fixed C to mycorrhiza.^[1] These costs are typically offset by increased nutrient uptake (and hence increased total photosynthesis), but reports of

negative growth responses to mycorrhiza, particularly arbuscular mycorrhiza, are not uncommon.

Considerable interest has been generated by the suggestion that mycorrhiza may permit the transfer of C between plants. Individual fungi may infect roots of different plants, potentially linking these plants into a common mycelial network. It has been suggested that this may permit C fixed by one plant to flow through mycelial links into other plants.^[6] Some achlorophyllous plants apparently obtain all of their C from such mycorrhizal linkages.^[1] Evidence for flow of C between photosynthetic plants remains equivocal because of difficulties in demonstrating net C flow^[6,7] (as opposed to gross C flow, which has been clearly demonstrated). If such interplant C transfer does occur, the ecological importance of such transfer in increasing seedling growth remains to be quantified.

INFLUENCE ON SOIL ECOSYSTEMS

The interactions between mycorrhiza and soil microorganisms can be complex. Mycorrhiza can serve as an important channel for C flow from plants to soil, potentially increasing microbial biomass or altering microbial community composition. At the same time, mycorrhizal fungi may compete with some saprophytes for soil nutrients or may produce antibiotic compounds that inhibit the growth of bacteria and fungi. The outcome of mycorrhiza–microbial interactions appears to depend both on the mycorrhizal and microbial species involved and on soil factors.^[8] One group of bacteria, the so-called mycorrhization helper bacteria, appears to enhance mycorrhizal infection of plants.

Studies on the influence of mycorrhizal fungi on decomposition drew conflicting results. Mycorrhizal fungi may inhibit decomposition (the so-called Gadgil effect) through competition with or direct inhibition of soil saprophytes.^[1] Alternatively, mycorrhizal fungi may actively participate in the decomposition (increasing the overall rate) or may enhance the activities of some saprophytes through the exudation of C-containing compounds.^[8]

SEEDLING INFECTION

Mycorrhizas are a horizontal symbiosis: each sexually produced generation of plants must obtain their own symbiotic partners independent of the parent plant. This is an important consideration, as a lack of mycorrhizal fungi can greatly hinder the establishment of plants. Limitation due to a lack of mycorrhizal fungi has been clearly observed in the failure of ectomycorrhizal trees to establish in regions where ectomycorrhizal vegetation is nonnative.^[1] Low levels of ectomycorrhizal fungi can also be an important limitation on even relatively small-scale disturbed sites.^[9] On sites where mycorrhizal inoculum is otherwise limiting, seedlings may have increased infection near established

ectomycorrhizal plants.^[9] Arbuscular mycorrhizal fungi may be more ubiquitous in secondary succession; however, these fungi are often absent in early primary successional sites (e.g., glacial forefronts, sand dunes, and strip mines). Even where mycorrhiza are uniformly present, there may be patchiness in the effectiveness of mycorrhiza at increasing plant growth.^[9,10]

Efforts to manipulate mycorrhizal fungi to increase forest productivity have had mixed success. Clear benefits of ectomycorrhizal inoculation are observed when planting tree seedlings on particularly harsh sites or sites with no native ectomycorrhizal fungi. However, under more typical forest conditions, inoculated strains of fungi are often out-competed by native fungi and may have limited benefits for forest production.^[1]

CONCLUSION

Mycorrhizas are involved in every aspect of forest soil ecology: they are central to plant nutrient uptake, they can short-circuit the N cycle, they participate in primary weathering of soil nutrients, and they provide a major input of C into the soil ecosystem. In addition, a lack of mycorrhizal fungi may limit the ability of forest tree species to establish, slowing forest succession on disturbed sites. At least a basic understanding of mycorrhiza is therefore critical to understanding both soil and plant ecology. A number of reviews are available for further reading.^[1,11,12]

Mycorrhizae: Soil Quality

Ibrahim Ortaç

*Department of Soil Science and Plant Nutrition, University of Cukurova,
Adana, Turkey*

Abstract

Soil is a dynamic and complex natural system, which is interactively regulated by physical, chemical, and biological properties and processes to provide ecosystem services including crop production. The soil quality as the critical component of the ecosystems is associated with soil's usefulness or performance to environmental quality as well as food quality. Soil quality is related to the development of many soil properties such as providing soil health, reflecting the fitness of a soil body, supporting water quality, sustaining plant productivity, and promoting human health. Soil is a sink for soil organic carbon (SOC). SOC, infiltration, aggregation, pH, microbial biomass, nitrogen forms, topsoil depth, conductivity or salinity, and available nutrients are the important indicators for soil quality. Mycorrhizal fungi also have an effect on soil quality in terms of increase in SOC, aggregation, nutrient uptake, and also increase in soil capacity for better health. The strength of the mycorrhizal association and its relationship with soil structure depends on root morphology and mycorrhizal hyphae. Arbuscular mycorrhizal fungi inoculation often increases the success of the ecological restoration as well. Mycorrhizal fungi are also effect on the soil function and capacity to increase productivity, resilience, and health functions. Also mycorrhizae increase SOC content, rhizosphere fertility, aggregation, porosity, and bulk density and reduce the stress factors that are all increase the soil quality.

WHAT IS SOIL QUALITY?

Soil is a dynamic and complex natural system, which is interactively regulated by physical, chemical, and biological properties and processes to provide ecosystem services including crop production. Soil as part of natural systems is a basis for life and habitat for soil organisms, i.e., plants. Soil's ability and functions in ecosystem to sustain plant and animal productivity and to maintain or enhance water and soil quality are critically important for human health and habitation. The soil quality as the critical component of the ecosystems is associated with soil's usefulness or performance to environmental quality as well as food quality. Soil has a significant contribution on filter of water and nutrient cycles and buffer of the soil reactions. Karlen et al.^[1] indicated that organic matter, infiltration, aggregation, pH, microbial biomass, N forms, topsoil depth, conductivity or salinity, and available nutrients are the important indicators for soil quality. Moreover, biological activity, enzymes, total organic carbon (C) and nitrogen (N), cation exchange capacity, aggregation, bulk density, and water retention and release capacity are very sensitive and important indicators of soil quality.^[2] Although there is not a complete consensus that has yet reached on the definition of soil quality, soil quality is usually related to soil organic matter (SOM) content, number and diversity of organisms, microbial by-products, hydrologic characteristics, aggregate stability, etc.

Aggregation Is a Very Important Parameter of Soil Quality

The dynamics of soil aggregate characteristics are often associated with changes in management practices and environment. Generally, soils in harsh environment are characterized by poor and compacted soil structures, low water-holding capacity and SOM content, and widespread nutrient deficiency. For a successful crop production or vegetation, it is necessary to improve soil quality and the ability of the plant's adaptation.^[3]

Management of SOM is important to maintain soil quality including soil physical characteristics. Soils, in general, have varied C storage capacity and aggregate size distribution. Soil organic carbon (SOC), as the main component of SOM, is an important determinant of the soil physical quality influencing water-holding capacity, porosity, aggregation, and fertility.^[4] The SOC content with other essential nutrients directly affects the production of biomass by improving soil quality.^[5] Kavdir and Smucker^[6] reported that soil structure influences several important soil functions such as soil productivity, biological activity, root growth, soil stability, and nutrient cycling as well. Borie et al.^[7] reported that soil structure stability is strongly influenced by the nature and content of SOM. Moreover, land use and management practices influencing SOM content are determinant of soil aggregation. Soil aggregates especially both macro- and

microaggregates exhibited a significant positive relationship with SOC and particulate organic matter.^[8]

WHAT IS THE ROLE OF MYCORRHIZAE IN SOIL?

Arbuscular mycorrhizal fungi (AMF) are the largest symbiotic associations between plants and fungi, which make significant contribution on physical, chemical, and biological aspects of soil quality through AMF hyphae extending into the rhizosphere and thereby improving the absorption of nutrients especially phosphorus (P) and micronutrients.^[9–11] The establishment of mycorrhiza causes changes in the physiology of the host plants. Like other soil microorganisms, AMF act as ecosystem engineers on roots and root surface of the plants. The AMF as soil microorganisms play a contributory effect on soil aggregate formation because of the symbiosis that significantly changes the root functioning.^[12] Thus, mycorrhiza has a significant impact on soil resilience, which is also an important component of soil quality.

Several studies have reported that soil biology especially mycorrhizal fungi significantly influences soil fertility and soil quality. However, the study on applied mycorrhizae is very new avenue in the field of soil quality research. The AMF also influence other soil functions, such as C, N, and P cycling to support plant growth and nutrition in the agroecosystems. Mycorrhizal inoculated plants are effective competitors in P-limited soil conditions. Several studies reported that mycorrhizal associations improve soil structures and increase uptake of nutrients and water through the extension of AMF hyphae distribution within the rhizosphere.^[9–11] Medina and Azcon^[3] suggested that soil amended with mycorrhizal fungi inoculation can be used as a successful biostrategy to improve plant performance in P-deficient soils under Mediterranean conditions. As shown in Table 1, mycorrhizal inoculation under field conditions increased the N, P, and K contents of sweet corn.

Mycorrhizal inoculation has been found to decrease the concentrations of salts and electrical conductivity of the

soil.^[14] The AMF colonization can also improve plant tolerance to stress conditions caused by drought and salt. Cekic et al.^[15] showed that under different salt level applications, mycorrhizal inoculation increased relative water content, P, total chlorophyll, and carotenoid content of pepper plants.

Mycorrhizae and Roots Effect on Soil Quality

Soil quality is also related to the rhizosphere beneficial microorganisms, such as AMF and bacteria. The AMF are an active and major component of the soil microbial community and have an important role on soil quality. Barea et al.^[16] indicated that symbiotic mycorrhizal associations are fundamental in optimizing plant fitness and soil quality. The AMF symbiosis has been proposed as one of the most effective mechanisms of plant heavy metal tolerance and water stress avoidance due to their effect on rhizosphere physical, chemical, and biological activities.^[10] The AMF are expected to have a synergistic effect on crops by improving the soil quality. The potential role of AMF in soil quality is related to improved soil physical properties.^[17] The contribution of mycorrhizal inoculation to the SOC content and aggregate formation depends on roots and hyphae productivity, roots and hyphae turnover rates, and their exudation. They improve soil quality by binding microaggregates and primary soil particles together and consequently resulting in: 1) improved soil structure; 2) increased water infiltration and retention; and 3) reduced soil erosion by minimizing leaching and runoff, while making them available to plants. As expected, plant roots are different and have significant effect on soil aggregation. Plant roots and AMF have direct and indirect binding effects on soil aggregate formation and stability. Jastrow et al.^[18] have provided the evidence related to the direct effects of mycorrhizal hyphae on soil aggregation. Soil aggregates play an important role in sequestering and stabilizing SOC.^[19] Other soil properties are also affected by plant roots and rhizosphere by significantly changing the soil physical, chemical, and biological properties.^[20]

Nadian et al.^[21] demonstrated that colonized Berseem clover (*Trifolium alexandrinum* L.) root length was improved by 20%, as soil aggregate diameter increased. Six et al.^[22] indicated that plant roots influence soil structure in diverse ways such as through root exudation, which includes polysaccharides that help to bind microaggregates and clay particles, and also through root pressure and penetration, which help to increase the proportion of stable aggregates through root entanglement. Mycorrhizae inoculated root also has mycorrhizosphere, which expanded rhizosphere volume and improved soil aggregate formation. The adherence of soil particles and sand grains on the root via AMF mycelia was pictured by Ortaş in field grown sorghum plant (Fig. 1).

The strength of the mycorrhizal association and its relationship with soil structure depend on root morphology^[24]

and mycorrhizal hyphae. AMF inoculation often increases the success of the ecological restoration.^[25] Rillig^[12] indicated that AMF are one of the important factors of soil quality through their effects on soil ecological interactions and their contributions to maintaining soil structure. However, AMF contributions on soil physical development depend on several factors and have a significant effect on ecosystem services. The ecosystem services provided by AMF are based on the modification of the root morphology and development of a complex ramified mycelia network in soil. These interactions improve plant–soil adherence and soil stability (binding action and improvement of soil structure), which in turn increase mineral nutrient and water uptake contributions by plants. It has been demonstrated that the mycorrhizal mycelial network can have a binding action on the soil and improve soil structure.^[26–28]

A major contribution of AMF in soils is their role on the maintenance of soil structure and plays a significant role in maintaining soil quality. The elongation of AMF from the mycorrhizal root to soil is a complex and ramifying network into the surrounding soil that can reach up to 30 m of fungal hyphae per gram of soil.^[29,30] Fig. 2 shows the adherence of soil particles and sand grains on the roots via AM mycelia in soil aggregation conceptual diagram.^[23]

Organic amendment and mycorrhizae are the well-known aggregate building agents.^[17] Extensive soil-based mycelium of fungus around roots can help soil aggregation processes (Fig. 3).

Mycorrhizal Hyphae, Glomalin, and Soil Quality

AMF enhance soil aggregate stability due to the production of extraradical hyphae and a protein known as glomalin. Glomalin, a brown to red–brown colored glycoprotein produced by AMF, is a major component of SOM that is defined operationally by the extraction method.^[31] The AMF, fed on C, found living on plant roots and appear to be the only producer of glomalin. A laboratory procedure reveals glomalin accumulation on soil aggregates as the green material (Fig. 4). Wright and

Fig. 2 Aggregate formation by the AM mycelia.

Source: From Ortas, unpublished data.

Upadhyaya^[32] have shown a strong non-linear relationship of the AMF hyphae product “glomalin” with water-stable aggregates across several soil types.

Glomalin was reported to be a non-water soluble, highly persistent glycoproteinaceous substance^[32] produced in mycorrhizal fungal cell walls, and it remains in soil after hyphae died.^[33] A strong correlation has been found between glomalin and water-stable aggregates in a wide variety of soils where organic material is the main binding agent.^[12,35] Wright and Upadhyaya^[36] indicated that increased aggregate stability, which leads to better soil structure, in turn, leads to control soil erosion for better plant production.

Bedini et al.^[37] showed that the secretion by AMF glomalin contributes to soil stability and water retention. Furthermore, it has been indicated that higher levels of

Fig. 3 Mycorrhizal hyphae through soil profile.

Fig. 4 Glomalin under microscope.
Source: From Nichols.^[34]

glomalin increase water infiltration, improve porosity and air permeability, better root development, improve microbial efficiency, and increase resistance to surface sealing and erosion. Driver et al.^[33] indicated that glomalin is thought to be deposited in soil by the degradation of extraradical hyphae of AMF. Bedini et al.^[37] indicated that (AM) fungi are key organisms of the soil–plant system, influencing and contributing to soil aggregation and soil structural stability by the combined action of extraradical hyphae and of a hydrophobic proteinaceous substance named glomalin. Rillig et al.^[38] shown that AMF hyphae and their glomalin products had significant contribution on water-stable aggregates of soil.

Treseder and Turner^[39] postulated that the role of glomalin in the ecosystem is not very clear and should be studied thoroughly under long-term and diverse management systems. Glomalin as a strong cementing agent is produced by a beneficial fungus that grows on plant roots. When hyphae stop transporting water, their protective glomalin sloughs off into the soil, where it helps soil build defenses against degradation and erosion and boosts its productivity.

As mycorrhizae produce enzymes (such as alkaline phosphatase), the activity of phosphatase can increase plant nutrient uptake as well.^[40] Phosphatase enzymes

are developed by plants for an effective P acquisition and possibly for N and less mobile micronutrients.

EFFECT OF MYCORRHIZA INOCULATIONS ON SOIL QUALITY UNDER LONG-TERM FIELD CONDITIONS

Long-term effects of mycorrhizal inoculation (after 14 years) on soil quality were presented in Table 2. Water-stable aggregation (WSA) had significantly affected by the organic (mycorrhiza + compost 10 ton ha⁻¹) and inorganic fertilizer treatments after 14 years' long-term experiment and ranged from 71.1% to 87.6%. The highest WSA was observed in compost + mycorrhizae treatment (87.6%), whereas the lowest WSA was found in control treatment (71.13%); mineral fertilizer has 74.6% of WSA. Mean weight diameter (MWD) of aggregates increased by 44% under the mycorrhizae + compost treatment as compared with the control.

Bedini et al.^[37] showed that MWD values of soil aggregates were positively correlated with the values of total hyphae length and hyphae density of the AMF. They also showed that the MWD of macroaggregates was significantly higher in mycorrhizal inoculated soils as compared to the non-mycorrhizal soils. Ortas et al.^[17] showed that the high values of MWD were associated with mycorrhizal inoculation rather than with application of organic fertilizer and that the MWD depended more on mycorrhizae application than on SOC content. Wilson et al.^[30] also reported that AMF abundance was a dominant factor affecting variability in soil WSA and MWD. The development of soil structure and the dynamics of WSA in many soils are closely related to the SOM cycling and the magnitude of root growth and mycorrhizal hyphae.^[41,42] Smith and Read^[10] concluded that the contribution of mycorrhizal root plus hyphae on aggregation is more than those of the hyphae alone, and that under pasture, the contribution of root and hyphae to WSA increases with increase in SOC content.

There were also significant differences in SOM content among the treatments (Table 2). The SOM content was 2.01% and 2.31% for chemical fertilizer and compost + mycorrhizae treatments, respectively, as compared with the SOM content in control (1.50%). Increasing SOM increases

Table 2 Effect of mineral fertilizer and mycorrhizae + compost application on soil properties after 14 years' long-term field experiment.

	SOM (%)	Bulk density (pb; g cm ⁻³)	Total porosity (St; %)	Soil-available water (cm ⁻³)	WSA (%)	MWD
Treatments						
Control	1.50	1.46	45	8.69	71.13	1.47
Mineral fertilizer	2.01	1.47	48	9.45	74.72	1.43
Mycorrhizal + compost	2.31	1.31	53	11.48	87.60	2.12

Source: From Ortas, unpublished data.

aggregate stability, infiltration, nutrient mineralization and availability, and cation exchange capacity. It suggests that mycorrhizal inoculation increased SOM content, which is directly related to soil quality. According to Harris et al.^[43] soil quality assessment scorecard, SOC has high score range. Soil bulk density, porosity, and soil water availability were significantly affected by mycorrhizal inoculation compared with the chemical fertilizer treatment.

There were also significant differences in total porosity among the treatments. As discussed earlier, Ortas et al.^[17] showed that soils treated with the compost + mycorrhizae organic fertilizers have the highest total porosity (St). The porosity was 45%, 48%, and 53% for control, chemical fertilizer, and compost + mycorrhizae treatments, respectively (Table 2).

Soil quality is related to the development of many soil properties such as providing soil health, reflecting the fitness of a soil body, supporting water quality, sustaining plant productivity, and promoting human health. Mycorrhizal fungi are also effect on the soil function and capacity to increase productivity, resilience, and health functions. Also mycorrhizae increase SOC content, rhizosphere fertility, aggregation, porosity, and bulk density and reduce the stress factors that are all increase the soil quality. Accordingly, it seems that mycorrhizal fungi have significant contribution on soil quality development. Usually, soil physical and chemical components were used for soil quality assessment; it may be possible to use mycorrhizae as a biological component as well. Usually, healthy soils have a rich diversity of soil useful microorganisms including mycorrhizal fungi. Mycorrhizal infection and spore germination can also be used as a soil quality indicator.

Nanofertilizers

Ruiqiang Liu

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

The development and application of new types of fertilizers using nanotechnology are one of the potentially effective options for significant enhancement of the global food production. This entry summarizes reviews related to either engineered or natural nanomaterials, which improve overall plant growth and could be used as nanofertilizers for increasing agronomic yields. A list of the relevant nanomaterials is presented, and the entry is focused on chemical composition, particle size, particle concentration applied, plant species, and plant growth enhancements. In addition, this entry classifies nanofertilizers into the following four categories: macronutrient nanofertilizers [e.g., apatite nanoparticles (NPs), calcium carbonate NPs, and magnesium oxide NPs], micronutrient nanofertilizers (e.g., iron oxide NPs, manganese oxide NPs, zinc oxide NPs, and copper oxide NPs), nutrient-loaded nanofertilizers [zeolites, silica NPs, and carbon nanotubes (CNTs)], and plant growth stimulating nanomaterials (titanium oxide NPs and CNTs). Each category is discussed for its own specific importance, research direction, and requirements in new fertilizer development. This entry suggests that development of nitrogen and phosphorus macronutrient nanofertilizers are a high research priority for sustainable agriculture and environmental protection.

INTRODUCTION

The capacity of arable land to sustain human has increased from 1.9 to 4.3 person ha⁻¹ between 1908 and 2008. This increase is partly due to the invention and application of synthetic mineral fertilizers. Hence, given the limited additional arable lands and scarce water resources in the world, the development and application of new types of high-efficiency fertilizers are among the practical options for feeding the projected 9.6 billion population (a ~30% increase from 2012) by 2050 without seriously damaging ecosystems and the environment. Nanotechnology is a promising approach in new fertilizer development. Indeed, some new findings, as seen in this entry, in nanotechnology research have revealed encouraging perspectives in this regard. So, the major objective of this entry is to analyze and synthesize the knowledge on these nanoparticles (NPs) and nanomaterials, which enhance plant growth and yields while reducing the risks of environmental disruptions associated with the conventional fertilizer uses (such as eutrophication or nitrate contamination). These nanomaterials are potentially important as innovative fertilizers to meet challenges of food security and environmental protection.

Nanomaterials and Nanofertilizers

Nanomaterials are defined as materials that have a single unit, with size between 1 nanometer (nm) and 100 nm, in at least 1-D. Accordingly, nanofertilizers are either

nanomaterials that can supply one or more nutrients to the plants and enhance plant growth and yields or those that can improve the performance of conventional fertilizers but do not directly provide crops with nutrients. For convenience of discussion in this entry, the former is collectively called nanofertilizers and the latter as nanomaterial-enhanced fertilizers. Furthermore, nanofertilizers can be classified as macronutrient nanofertilizers and micronutrient nanofertilizers. Compared with the conventional nanofertilizers, these nanofertilizers are expected to significantly improve crop growth and yields, to enhance the efficiency of fertilizer use and reduce nutrients losses, and/or to minimize the adverse environmental impacts.

MACRONUTRIENT NANO FERTILIZERS

Macronutrient nanofertilizers are chemically composed of one or more macronutrient elements such as nitrogen (N), phosphorus (P), potassium (K), magnesium (Mg), and calcium (Ca), thus being able to supply one or more of these essential elements to plants. Total global consumption of conventional macronutrient fertilizers (N + phosphorus pentoxide + potassium oxide) was estimated at 176 million ton (Mt) in 2011 and is projected to increase to 263 Mt in 2050,^[1] indicating the critical role of these macronutrient fertilizers in agriculture and in food production. Moreover, due to the low efficiency (30–50%) and heavy application of these fertilizers, significant amounts of these nutrients

Fig. 1 A transmission electron microscopic image of hydroxyapatite NPs.

Source: Adapted from Liu & Lal.^[2]

(N and P) end up in surface and groundwater bodies, disrupting aquatic ecosystems and threatening human health. Therefore, an urgent and practical research direction is to develop highly efficient and environmentally friendly macronutrient (especially N and P) nanofertilizers to replace the conventional nanofertilizers for sustainable food production and environmental protection.

Liu and Lal^[2] synthesized a new type of hydroxyapatite ($\text{Ca}_5(\text{PO}_4)_3\text{OH}$) NPs of ~16 nm in size (Fig. 1) and assessed the effect of NPs as a P fertilizer on soybean (*Glycine max*) growth in a greenhouse experiment. Results showed that NPs' application increased the growth rate and seed yield by 32.6% and 20.4%, respectively, compared to those of a regular P fertilizer. Biomass productions were enhanced by 18.2% (aboveground) and 41.2% (belowground), respectively. Data revealed that soybean plants could absorb apatite NPs as an effective P nutrient source for normal metabolism. In addition, the NPs may also have supplied Ca nutrient. Using apatite NPs as a new class of P fertilizer can potentially enhance agronomical yield, increase efficiency of P application, and reduce risks of water eutrophication. Liu et al.^[3] and Delfani et al.^[4] reported using CaNPs (calcium carbonate, 20–80 nm, 160 mg L⁻¹ as Ca) and MgNPs (500 mg L⁻¹ as Mg, others unknown) that Ca and Mg fertilizers are used for enhancing peanut (*Arachis hypogaea*) and black-eyed pea (*Vigna unguiculata* subsp. *unguiculata*) growth.

MICRONUTRIENT NANOFERTILIZERS

Plant micronutrients include iron (Fe), manganese (Mn), zinc (Zn), copper (Cu), Mg, and molybdenum (Mo). Compared

with the plant macronutrients, only trace levels of micronutrients are required for healthy growth of crops as shown in the composition of Hoagland solution.^[5] Micronutrients are often added to the N, P, and K fertilizers at small amounts as soluble salts for crop uptake. Micronutrients in these composite fertilizers usually provide enough nutrients and cause no environmental damages. However, plant availability of the applied micronutrients may become low, and micronutrient deficiency may occur in some soils with alkaline pH, coarse texture, or low organic matter content.^[6] Micronutrient nanofertilizers are expected to enhance uptake by plants even in such worst-case scenarios. Table 1 includes a list of micronutrient NPs that have been tested and have exhibited potentials as micronutrient nanofertilizers.

NANOMATERIAL-ENHANCED FERTILIZERS

Nanomaterial-enhanced fertilizers are defined as these nanomaterials, when loaded with plant nutrient(s), aimed at increasing plant-uptake efficiency of the nutrient(s) and/or reducing the adverse impacts of fertilizer application, but the nanomaterials themselves do not contain or supply the targeted nutrient(s). An important example of this type is nutrient-loaded zeolites.

Nutrient-loaded Zeolite Nanofertilizers

Zeolites' particles are often not present at nanoscales. But the arrangement of aluminum and silicon in the 3-D framework of silicon tetroxide and AlO_4 tetrahedra of zeolites creates the channels and cages that are within nanoscale (0.3–10 nm in diameter). As a result, zeolites are termed as materials with nanostructures. Due to their unique nanoporous properties, zeolites often have extremely high specific surface area, high cation exchange capacity, and high selectivity toward plant macronutrients (potassium ion and ammonium ion) over others. Thus, these plant-essential elements may be absorbed onto zeolite exchange sites, where the nutrients can subsequently be released slowly for plant uptake, thereby reducing migration of these nutrients into groundwater or runoff and decreasing the potential for environmental pollution. Moreover, volatilization of gaseous N [e.g., as ammonia or dinitrogen (N_2)] can also be reduced, as the adsorbed N is unavailable for conversion to these gaseous phases by soil microbes. So far, zeolites have been an ideal candidate for improving N efficiency, reducing nutrient losses, and eliminating environmental risks.^[13] A few examples showing the benefits of nutrient-loaded zeolite nanofertilizers under field conditions are provided in several references.^[14–17]

Other Nanoparticulate Fertilizer Carriers

Laboratory observations indicate that some NPs (silica, Fe oxides, carbon-coated Fe, and polymers) can enter

Table 1 NPs reportedly enhanced plant growth by providing micronutrients and could be used as micronutrient fertilizers.

Nutrient provided	NP type, particle size, and concentration	Test plant, method, and medium	Growth enhancement		
			Over control 1 (no target nutrient)	Over control 2 (regular fertilizer with target nutrient)	Other factors
Micronutrient Fe	Superparamagnetic iron oxide NPs, ^[7] Fe ₃ O ₄ , 18.9–20.3 nm, 30, 45, and 60 mg L ⁻¹	Soybean, nutrient solution, perlite medium, 7-day greenhouse test	No reported	Fe-EDTA, chlorophyll content, (1.1) ^a at 30 mg L ⁻¹ and (1) at 45 mg L ⁻¹ but (0.8) at 60 mg L ⁻¹	N/A
Micronutrient Mn	Metallic Mn, ^[8] 20 nm, 0.05, 0.1, 0.5, and 1.0 mg L ⁻¹	Mung bean (<i>Vigna radiate</i>) plant, nutrient solution, perlite medium, 15-day in growth chamber	Root length (1.4–1.5), shoot length (1.2–1.4), dry weight (1–2), chlorophyll (1.1–1.8), and carotenoid (1.1–2) content, photosynthesis rate (1.1–1.7)	MnSO ₄ , root length (1–1.6), shoot length (1.1), dry weight (1–2), chlorophyll (1–1.6), and carotenoid (1.1–1.4) content, photosynthesis rate (1.1–1.3)	MnNPs did not show phytotoxic as MnSO ₄ did
Micronutrient Zn	ZnO, ^[9] 20 nm, 1–2000 mg L ⁻¹	Mung bean and chickpea (<i>Cicer arietinum</i>) seedlings, agar medium, 60 hr in an incubator	Shoot height (1.3) and biomass (1.6), root length (1.9) and biomass (1.4) for Mung bean at 20 mg L ⁻¹ ZnNPs; (1), (2.8), (1.5), (1.3) for chickpea at 1 mg L ⁻¹ ZnNPs	No reported	ZnNPs at levels higher than the optimum showed phytotoxicity
	ZnO, ^[10] 10 nm, 400 and 800 mg kg ⁻¹ soil	Cucumber (<i>Cucumis sativus</i>), soil mixture, a life cycle, 53-day greenhouse test	Root dry mass (1.1–1.6), fruit starch (1.1–1.6), glutelin (0.9–2), Zn (1.7–2.5)		No negative effects of ZnNPs found
Micronutrient Cu	70% CuO and 30% Cu ₂ O, ^[11] 30 nm, 0.025, 0.25, 0.5, 1, and 5 mg L ⁻¹ as Cu	<i>Elodea densa planch</i> , 3-day incubation, water	Photosynthesis rate (1–1.4) at <0.5 mg L ⁻¹	CuSO ₄ ; photosynthesis rate (1.4–3) at <0.5 mg L ⁻¹ ; leaf Cu (5) at <0.5 mg L ⁻¹	CuSO ₄ inhibitory at all concentrations
Micronutrient Mo	Mo, ^[12] 100–250 nm, 8 mg L ⁻¹ , others unknown	Chickpea, seed-soaked 1–2 hr, a life cycle, soil, rhizosphere examination	Nodule number/mass (11/6.2), activity of antioxidant enzymes (1.9–2.6), symbiotic bacteria (1.9–3.2)	Not reported	Microbial treatment further enhanced the effects

^aThe enhancement value in parentheses represents chlorophyll content under NPs treatment/chlorophyll content under control, and so on.

plant tissues/cells and transport DNA and chemicals inside the tissues.^[7,13–21] These findings led many researchers to speculate on using these NPs to deliver nutrients to the plants as a new fertilizing or nurturing technique. However, there are no specific reports on using these NPs as nutrient carriers to enhance plant growth and productivity.

NEW NANOPARTICULATE PLANT GROWTH ENHANCERS WITH UNCLEAR MECHANISMS

There are a few reports on other types of NPs that could enhance plant growth although these particles do not contain any essential plant nutrients. Typical examples of this

type are titanium dioxide (TiO₂) NPs (TiNPs) and carbon nanotubes (CNTs).

Titanium dioxide NPs

Traditionally, titanium (Ti) was not regarded as an essential nutrient for plants. Additionally, soils usually contain high levels of Ti ranging from 0.1% to 0.9%, and an average of ~0.03 mg L⁻¹ Ti is often reported in soil solution.^[22] Thus, the application of Ti to soil is not necessary for agronomic production. However, a few reports^[23,24] indicate that TiNP application (on exposure to sunlight) may increase plant photosynthesis efficacy, enhance plant enzymes activity, and improve availability of N through chemical fixation of N₂ in the air, thereby promoting plant growth. There was

Table 2 Research needs for nanofertilizers.

Nanofertilizer type	Importance in food security and sustainable agriculture	Research direction	Other important research items
Macronutrient	Very important	N and P fertilizers with high fertilizing capacity, high efficiency, low leaching rate, and low risks of environmental contamination	
Micronutrient	Not important	High efficiency at extreme soil pH, or in soils with low organic matter content, or coarse texture	To compare with regular fertilizers in plant growth/yield enhancements
NP carriers	Important	Increasing N and P use efficiency and decreasing nutrient leaching	To present nanotoxicity study of any new type of nanofertilizers
Plant growth simulating NPs	Important	More evidence and mechanism clarification	

a report published in the 1970s showing that leaf spray of chelate Ti (1 mg L^{-1}) enhanced sugar and chlorophyll contents in apples (*Malus domestica*), grapes (*Vitis vinifera*), and sugar beets (*Beta vulgaris*).^[25] But negative effects of TiNPs at 4 g L^{-1} on seed germination have also been reported.^[26]

Carbon Nanotubes

Some reports^[27–29] indicate that CNTs in low doses could be stimulators of seed germination and plant growth. Khodakovskaya et al.^[27] proposed that the surface charges of CNTs affected growth and expression of water channel proteins in tomato, thereby enhancing water uptake and utilization efficiency.

RESEARCH NEEDS AND FUTURE DIRECTIONS

Review of the nanotechnology research on enhancing plant growth and yield indicates potential applications of those nanofertilizers for crop production. The importance, research direction, and research priority of each type of nanofertilizers are summarized in Table 2.

CONCLUSION

Plants can utilize nutrient-containing NPs as essential mineral nutrient sources through roots or leaves, thereby maintaining or enhancing their metabolism, anti-pathogen capacity, growth, and yield. Some of these NPs lead to better performance than associated conventional fertilizers. Moreover, some inert NPs, when augmented with nutrients, can either enhance the fertilizer use efficiency or minimize environmental disruptions. Some other inert NPs, although supplying no nutrients, can improve crop yields by enhancing their physiological activities such as photosynthesis or water uptake/uses. Therefore, research and development of nanofertilizers is fairly important to global sustainable development. Among these, macronutrient nanofertilizer

and macronutrient-loaded NPs (especially for N and P) have a high research priority.

Natural Resources: Interaction with Soil

Dennis J. Greenland

University of Reading, Reading, U.K.

Abstract

To preserve life as we know it, it is essential that we conserve our soils and increase their productivity. In the past, there have been several examples of the end of civilizations because of failure to control soil degradation. Only by careful conservation of our soils, and technical innovations to increase their productivity while avoiding environmental damage, can a similar fate for our modern civilization be prevented.

INTRODUCTION

It is impossible to overestimate the importance of soils. All life on earth, except for fish and other aquatic species, depends on the soil. The very first living things may have evolved in the oceans, but emergence onto the land followed and developed because of the unique properties of the soil. The relation of humans to the soil has long been recognized in religious beliefs. Hillel^[1] traces these relationships in Jewish beliefs, in the sayings of Buddha, in the Koran, and in early Greek civilization. The common theme is that earth is the mother of life. In some places, the earth had to be made fertile by water. In ancient Egypt, the waters of the Nile were worshipped, and in India, the Ganges is known as the Mother of India. But in China, the Huanghe (formerly known as the Yellow River) is called the Sorrow of China because of the huge quantities of silt eroded from the Loessial soils in its catchment and the fearsome floods that have devastated the downstream areas for thousands of years.

It is not only the interaction of soil with water that creates its unique and essential properties but also its interaction with all natural resources. The soil has been rightly described as the attic of the earth sciences and the basement of the plant sciences. Soil is formed from rocks, and its interaction with air and water enables plants to grow. Forests and grasslands, as well as the crops on which we live, are all dependent on soil. To grow, plants need air, water, and nutrients. Soil is the great storehouse of the nutrients essential for life. Not only does soil contain all essential nutrients, but it also exchanges them with soil solution in such a way that there is seldom an excess and normally a sufficient amount to allow the development of a varied population of invertebrates and microorganisms.

Nitrogen is an exception. It is seldom present in sufficient quantities within the rocks from which the soil was formed to support an active soil population. However, among the earliest organisms were those with the ability to process atmospheric nitrogen. The presence of air within

the soil provides the nitrogen for these organisms; as these organisms die, their remains are attacked by other organisms and their nitrogen partially assimilated and partially added to the nitrogen in soil organic matter.

THE UNIQUE PROPERTIES OF SOILS

To support life, soil must enable water to be stored, so that it does not drain away under the pull of gravity but can be available to organisms in and on the soil and be retained for plant use. The soil must also allow air to move into it, so that oxygen is available and carbon dioxide may escape. This requires the soil to have a structure consisting of large cracks and pores; large pores will drain under gravity (transmission pores), and smaller pores will hold water against gravity but not hold it so strongly that plants are unable to use it (storage pores).

Such a structure is possible because of the wide range of soil particle sizes, from fine [<2 micron equivalent spherical diameter (μ esd)] clay particles to silt particles (2 – 20μ esd) and larger sand, gravel, and stones ($>20 \mu$ esd). The physical forces associated with swelling and shrinkage—due to wetting and drying and freezing and thawing—create cracks and pores within the soil, between which are denser aggregates containing a wide range of smaller pores. Worms and other soil animals also create relatively large transmission pores, and fungi, bacteria, and plant roots release mucilaginous material to coat the sides of the pores and strengthen them against subsequent compression.

Thus, the special structure of soil essential to the development of the natural vegetation is built. This structure is able to provide water and nutrients, allow gases to move in and out, and provide channels through which plant roots can grow and seedlings can emerge. Once the vegetation is established, it contributes to the soil by adding organic matter as litter decays and nutrients are recycled. The organic matter feeds the soil population and contributes

to the exchange of nutrients between soils and organisms. When the organic matter decomposes, it releases nitrogen, sulfur, and phosphorus contained within to feed other organisms.

Among the materials that make up soil organic matter are many acidic compounds (e.g., humic and fulvic acids), which adsorb important nutrient cations and exchange them with others in the soil solution.

When clays are formed by minerals weathering, they too retain nutrient cations at their surfaces. These cations are held either by negative charges—which develop from isomorphous replacement of higher-charged cations with lower-charged cations from within the clay lattice—or by dissociation from acidic groups on the surfaces of hydrous oxides.^[2]

THE FORMATION AND DEGRADATION OF SOILS

Soils tend to be formed slowly over thousands of years, as rocks weather, organic matter accumulates, and as eluviation, sedimentation, and erosion occur under the natural effects of climate and topography, modified by the influence of vegetation.^[3,4] These processes which have given rise to the fertile soils of the world may be drastically modified by human intervention, which can both enhance and reduce the ability of soils to sustain life on earth. Soils are used in many ways to improve human life, but their misuse or exploitation can also destroy the essential features that have made them the essence of life on earth.

SOIL AND CIVILIZATION

Two hundred years ago, Malthus^[5] warned the world of the dangers that arise as the demands of a growing population place increasing stress on world resources. Evans^[6] has traced how the world population has grown and how it has produced the food to sustain it. Until the world population reached 3 billion in 1960, the main source of greater food production was the cultivation of more land. Since 1960, the world population has doubled. The extra food needed to sustain a population of six billion in 1999 had come from increased crop yields, associated with higher-yielding plant varieties and the use of fertilizers and pesticides—techniques of the Green Revolution. There is scope for further production increase where good quality water is available, more land can be irrigated, and the number of crops grown per year increased. The Food and Agriculture Organization (FAO) of the United Nations believes that there is still scope for more land to be cultivated for arable production,^[7] but Young^[8] and others believe that the FAO estimates are too high. Most good land was cultivated first; subsequently, agriculturists have been forced to develop poorer and more fragile land that is susceptible to degradation. Further, because the good land was close to cities and the cities have grown, the

alienation of land for buildings, roads, and factories has affected good land more than poor land.

Much of the essential resource for sustaining life has been lost by the alienation of good land and the degradation of poorer land. This is perhaps most vividly illustrated by erosion. The rate of natural erosion may be enormously accelerated by actions that expose the soil directly to rainfall, without the intervention of a forest or grass cover. Such actions mostly derive from deforestation to allow the land to be used for agriculture or animal production.^[8,9] Although there are several sources of soil degradation, erosion is the most widespread and that which most commonly leads to irreversible losses of productivity.^[10]

The continued intensification of land use that has led to increasing degradation of land and water supplies has brought the world closer to the Malthusian Precipice,^[11] where the rate of population growth exceeds the rate of increase in food production.

To preserve life as we know it, it is essential that we conserve our soils and increase their productivity. In the past, there have been several examples of the ends of civilizations because of a failure to control soil degradation.^[1,12] Only by careful conservation of our soils, and technical innovations to increase their productivity while avoiding environmental damage, can a similar fate for our modern civilization be prevented.

Nematodes

Christien H. Ettema

Soil Biology Group, Wageningen Agricultural University, Wageningen,
the Netherlands

Abstract

Nematodes are generally microscopic animals, belonging to the phylum Nematoda. They are very numerous, representing 80% of all multicellular animals. Nematodes live in soil, freshwater, and marine environments. In addition, they occur as parasites of vertebrate (including humans) and invertebrate animals (such as insects). Soil nematodes live in water-filled pore spaces or water films surrounding soil particles. A handful of soil contains thousands of individuals, dozens of species, and several feeding groups. Plant disease caused by nematodes results in billions of dollars lost worldwide. However, most nematode species are beneficial—they enhance plant growth by promoting nutrient cycling and contribute to biological control of plant enemies, including insects, fungi, and plant-parasitic nematodes.

HISTORY

Free-living (non-parasitic) nematodes were first discovered in 1656 A.D., when Borellus observed *Turbatrix aceti* in natural vinegar, using one of the first microscopes.^[1] In 1743, Needham gave the first account of a plant-parasitic nematode, *Anguina tritici*, from wheat galls. In the mid-19th century, nematology developed as an independent branch of zoology. Because the study of soil nematodes has been driven by the economic impact of plant parasites, free-living nematodes have comparatively received little attention. However, the most intensively studied nematode is the free-living *Caenorhabditis elegans*, which is considered a model for genomic, developmental, and neurobiological systems with relevance to all of biology.^[2]

CLASSIFICATION

Taxonomic Classification

As nematology is a relatively young science, nematode taxonomy is in great flux, with no single classification agreed upon by all taxonomists. Taxonomic classification is generally based on morphological characteristics, but molecular phylogenetic research challenges the resulting higher level classification.^[3] Usually, Nematoda are divided into two classes, the Adenophorea (Aphasmsidia) and the Secernentea (Phasmsidia), primarily based on the absence or presence of posterior sense organs, the phasmids. Examples of soil-dwelling orders are given in Fig. 1. A comprehensive overview of taxonomic literature is provided by Bongers.^[4]

Trophic Classification

The soil nematode fauna typically includes several trophic (feeding) groups. Nematodes may be bacterial feeders (predominantly Rhabditida, Araeolaimida, and Monhysterida), fungal feeders (Aphelenchida, Dorylaimida, and Tylenchida), plant parasites and plant associates (Tylenchida, Aphelenchida, and Dorylaimida), carnivores (Mononchida and Enoplida), omnivores (Dorylaimida), algal feeders (Chromadorida, Desmodorida, and Enoplida), and insect parasites (Rhabditida). Trophic groups are generally distinguished by the mouth structure and esophageal shape. However, as some taxa lack the typical anterior morphology, it is recommended that nematodes be identified to genus and classified trophically according to Yeates, Bongers, et al.^[5] A second note of caution is that unequivocal classification into trophic groups is not always possible, because of opportunistic feeding habits, life-stage dependent diets, or lack of dependable information.^[5]

Life History Classification

For environmental monitoring, soil nematodes are classified into five life history groups, ranging from r-selected “colonizers” (commonly members of Rhabditida) to K-selected “persisters” (mostly Dorylaimida). Their relative abundances are weighted using the maturity index, indicating the level of soil disturbance.^[6] However, the challenge remains to avoid ad hoc descriptions and establish clear cause-and-effect relationships between nematode community changes and soil disturbance.^[7] A bibliography on environmental monitoring with nematodes is provided by Bongers.^[8]

Fig. 1 The soil-dwelling nematode orders. Note that the order Aphelenchida is missing, as Ingham^[9] considered it a suborder (Aphelenchina) of the Tylenchida, following the classification used by Golden.^[10]

Source: From Ingham.^[9]

MORPHOLOGY

Nematodes are bilaterally symmetrical, non-segmented pseudocoelomates. Their body plan is simply a “tube within a tube.” The outer tube is the body wall, consisting of a flexible cuticle and longitudinal muscles, with which sinusoidal locomotion is achieved. The inner tube is the alimentary tract, which, starting at the anterior end (Fig. 1), consists of a stoma or stylet, esophagus, intestine, rectum, and anus. Nematodes are normally bisexual, but for some species reproduction is parthenogenetic

or hermaphroditic.^[11] Nematodes have excretory and nervous systems but lack discrete circulatory or respiratory systems. Internal structures are easily observed with substage lighting under a microscope. In the nematode life cycle, which depending on species and environment varies from 1 week to >1 year, the egg stage is followed by four juvenile stages before adulthood. In response to adverse environmental conditions (e.g., drought), nematodes may enter anabiosis, a state of metabolic dormancy that may last for years. Extensive information on nematode structure can be found in Bird and Bird.^[11]

BIOGEOGRAPHY

Distribution and Abundance

Soil nematodes are found in all biomes, with topsoil abundances ranging from 50,000/m² in Antarctic deserts^[12] up to tens of millions per square meter in temperate grasslands and deciduous forests.^[13] Generally, nematodes occur wherever there is moisture and food available. Because these resources have heterogeneous distributions, nematode populations are highly aggregated, which is a concern for quantitative soil sampling.^[14] Active migration is limited in range, but nematodes may be dispersed over long distances (notably in anabiotic form) by wind, water, insects, birds, and mammals.^[1]

Species Diversity

Less than 6000 terrestrial nematode species have been described, but it is estimated that there are at least 1,00,000 species.^[15] Species richness is generally greatest in temperate broadleaf forest (62 species per soil sample) followed by cultivated soil, grassland, tropical rainforest, temperate coniferous forest, and polar vegetation.^[16] The structural and functional implications of nematode biodiversity are being debated.^[17]

HARMFUL NEMATODES

Plant-parasitic nematodes can cause great damage to agricultural crops. Ectoparasitic nematodes stay outside the root and use their stylet to puncture root cells (e.g., the feeding nematode *Belonolaimus* and the stunt nematode *Tylenchorhynchus*). Endoparasitic nematodes enter the root and move around (the lesion nematode *Pratylenchus*) or stay in one feeding site (the root-knot nematode *Meloidogyne* and the cyst nematodes *Globodera* and *Heterodera*). The resulting root damage can cause wilting, stunting, nutrient deficiencies, and yield losses. Some species transmit viruses (*Longidorus*, *Trichodorus*, and *Xiphinema*). In other cases, nematodes may cause damage to above ground plant parts (the stem nematode *Ditylenchus dipsaci* and the wheat gall nematode *A. tritici*). Worldwide, nematode damage may amount to \$78 billion annually.^[18] Nematode problems of various crops and climates are reviewed by Nickle and Luc et al.^[19,20] An important observation is that low levels of root herbivory could promote plant growth by stimulating root branching and exudation, which in turn enhances rhizosphere microbial activity and nutrient availability.^[21]

Nematode control may include sanitary measures, crop rotation, use of resistant cultivars, application of nematicides and organic amendments, intercropping with nematode-antagonistic crops, and physical methods such as tillage, steaming, and solarization.^[22] Nematodes have

Fig. 2 A predacious nematode feeding on a gravid bacterivorous nematode. The predator itself is infected with *Pasteuria penetrans* (the “warts” attached to the predator’s cuticle are bacterial endospores).

numerous natural enemies including soil bacteria, fungi, predatory nematodes, and insects (Fig. 2),^[23,24] but soil communities are not easily manipulated for biological control. Promising results have been obtained with *Verticillium chlamydosporium*, an egg parasite of cyst and root-knot nematodes.^[25] The nematode-trapping fungus *Arthrobotrys* is commercially available and controls nematodes in cultivated mushroom and tomatoes.^[23]

BENEFICIAL NEMATODES

Microbial-Feeding Nematodes

Microbial-feeding nematodes (bacterivores and fungivores) may promote plant growth by enhancing nutrient mineralization, notably of nitrogen.^[26] As microbial-feeding nematodes have a higher carbon-to-nitrogen ratio than microbes, and low production efficiency, they mineralize the nitrogen immobilized in microbial biomass. In addition, they can stimulate microbial activity (and thus nitrogen mineralization) by reducing microbial competition, enhancing oxygen diffusion, and transporting microbial propagules to new substrates. Using knowledge of microbivorous nematode population dynamics, the application of organic amendments can be timed to optimize nitrogen availability to crops.^[27]

Predacious and Omnivorous Nematodes

By controlling microbivorous population, predacious (Fig. 2) and omnivorous nematodes prevent “overgrazing” of microbes and thereby indirectly control nutrient cycling processes.^[28] In terms of biological control, it is unlikely that predacious nematodes could significantly contribute to plant-parasitic nematode control.^[29] Their generation times are too long for a timely response to

plant-parasite population peaks, and there is an evidence that predacious nematodes prefer microbial feeding, not plant-feeding, nematodes as diet. Predacious and omnivorous nematodes may be useful indicators of soil ecosystem health, because of their long life cycles and sensitivity to disturbance.^[6]

Entomopathogenic Nematodes

Entomopathogenic (insect-parasitic) nematodes are successfully used in biological control of pest insects, including white grubs, leaf miners, and cockroaches.^[30] Entomopathogenic nematodes (order Rhabditida) carry a symbiotic bacterium. After penetrating the host insect, the nematode releases the bacterium, which kills the host within 72 hours, providing food to the nematode, which then multiplies inside the cadaver. Infective juveniles disperse to new hosts. (For detailed information on entomopathogenic nematodes, see Gaugler and Kaya.^[31])

METHODS

Methods for collection and extraction are reviewed by Nickle, Ingham, and McSorley.^[9,19,32] For ecological work with nematodes, useful methods are compiled by Wheeler et al.^[33] A bibliography of nematode identification keys is provided by Bongers,^[4] and an interactive diagnostic key to plant-parasitic, free-living, and predacious nematodes is found in <http://ianrwww.unl.edu/ianr/plntpath/nematode/key/nemakey.htm>.^[34]

Nematodes and Soil

Wilfrida Decraemer

Department of Invertebrates, Royal Belgian Institute of Natural Sciences,
Brussels, Belgium

Abstract

Soil nematodes and their communities are suitable as bio-indicators to assess soil health and environmental changes. They are abundant, functionally diverse, and present at all levels of the food chain; show different reproductive and survival capacities; and respond in different degrees to changes in the ecosystem such as resource enrichment or disturbance. They recycle nutrients by feeding on microorganisms and plants and facilitate uptake of minerals by plants. The succession status of the nematode soil community reflects a history of disturbance or restoration. Several indices and ratios have been introduced, e.g., the structure index that describes whether a soil ecosystem is matured (high index) or disturbed (low index) and the fungivore/bacterivore ratio as indicator of the dominant decomposition pathway. Understanding ecosystem functioning and stability is indispensable for a sustainable agriculture and environmental monitoring. Nematodes form a suitable tool to analyze the effects of altered conditions due to climate change, or other forms of disturbance. More cost-effective tools are developed taking advantage of next-generation sequencing of faunal assemblages and search for key genera/species with a known sensitivity or response to specific types of disturbance.

INTRODUCTION

Nematodes or round worms are a very abundant and diverse group of small, unsegmented, and mostly transparent thread-like worms, occurring in almost every habitat either as free-living or as parasites of plants and/or animals. They appear simple and conservative in their morphology but show an enormous plasticity to adapt to a wide range of conditions and habitats. For their active life and locomotion, they depend on moisture. However, many nematodes can survive harsh conditions in an anhydrobiotic state. Survival of soil nematodes is directly affected by soil moisture, relative humidity, and other environmental factors such as soil texture. Soil pore size influences the ability with which nematodes move through the soil interstices. Soil pH and temperature may also affect nematode taxa. Nearly, a quarter of the total number of nematode species described are free-living (about 12,000 species), the majority being from terrestrial habitats; many species remain to be discovered.^[1] Nematodes are typically amphimictic, having separate males and females. However, many species lack males and reproduce either by parthenogenesis (common) or by hermaphroditism (rare). Nematodes typically have an egg stage, four juvenile stages, and the adult stage. Most nematodes molt four times before becoming an adult. In some groups, one juvenile stage (usually J3) is more resistant to environmental stress and is therefore specialized for dispersal and for surviving harsh conditions; it usually represents the infective stage of most animal-parasitic forms. In free-living bacterial-feeding rhabditid nematodes,

this modified stage is called dauer (German for endurance) and may represent an alternative pathway to the normal development process. Many free-living species with dauers are dispersed by insects or other arthropods, a relationship known as phoresy. The nematode life cycle varies from a few days for many bacterivorous colonizers such as rhabditids to more than a year for longidorid plant ectoparasites.^[2] Females are usually oviparous, but in some groups, the eggs can hatch inside the female body (ovoviviparity), usually resulting in her death. Ovoviviparity can be induced in normally reproducing species by pollutants (e.g., sulfur dioxide).^[3]

Nematodes play a variety of roles. In agriculture, they are one of the major pests, e.g., in potato in Europe where the increase of world trade provides the associated risk of spread of the potato cyst nematode *Globodera* spp. as well as an increased threat to the use of resistant cultivars as a major tool in reducing damage caused by these species.^[4] Worldwide, but especially in the developing and transition countries, plant-parasitic nematodes (PPNs) including root-knot nematodes (*Meloidogyne* spp.) cause important yield losses (overall average of 12.3%) to cash and other crops (Fig. 1).^[5] It has been estimated that a single acre of soil from arable land may contain as many as 3,000,000,000 nematodes, and a single wheat gall formed by *Anguina tritici* contains approximately 11,000–18,000 nematodes, although as many as 90,000 have been recorded.^[6] Several nematode species are, on the contrary, very promising as natural antagonists against pest insects. Entomopathogenic nematodes (EPNs) of the families

Steinernematidae and Heterorhabditidae are associated with symbiotic bacteria (*Xenorhabdus* and *Photorhabdus*, respectively), which are able to kill the insect host usually within 24–48 hr.^[7] EPNs are harmless to the environment and men and are increasingly used as environmentally safe biocontrol alternatives for chemical control products. Free-living nematodes are used as bio-indicators of pollution in terrestrial and aquatic environments. Nematodes play a key role in soil and aquatic food webs because of their ubiquitous presence, overwhelming densities (typically 100 g of soil yields around 3000 nematodes) and diversity (sometimes compared to insects), their presence at different trophic levels (as plant feeders, secondary detritivores, predators, and omnivores), low mobility, their difference in sensitivity, and quick response toward diverse types of disturbances (Fig. 2).^[8,9] To facilitate interpretation in ecological studies, terrestrial nematodes were allocated into functional groups (guilds) based on feeding type and life history strategy.^[10] Nematodes are an essential component in food security and interact in a synergistic or antagonistic way with other organisms.^[11] Different types of soil properties, soil management (forestry, agriculture, natural habitat), vegetation, and environmental disturbance such as pollution have an impact on soil nematode community structure, making the latter an interesting tool to assess changes in soil conditions.

This entry aims to highlight 1) the role of soil nematodes in soil ecosystems and 2) their importance as soil health bio-indicators, a function that will increase in importance due to the impact of climate change, the decrease in the use of chemical pesticides, and major biodiversity and environmental concerns nationally and internationally, inducing the need for further development of soil ecosystem strategies to improve soil quality,

including the reduction of PPN pests and improvement of plant health.

NEMATODES AND SOIL

Soil nematodes can be used to untangle biological mechanisms in soil and serve as environmental monitoring tools. Nematodes play a central role in the soil food web, but information on free-living soil nematodes is rather small compared with that of economically important PPNs. The active life of nematodes in soil is primarily determined by soil properties such as soil texture and soil structure, available soil moisture, pH, temperature, organic matter, available food, and impact of other soil biota. A range of nematode community indices has been proposed for environmental monitoring.

Soil Texture, Soil Structure, and Moisture Regime

Most ecological studies relate nematode behavior to soil texture. Nematodes occur in a wide range of soils, but their distribution, horizontally and vertically, is mostly limited by soil moisture regime and food availability. Soil

structure (= arrangement of soil particles or aggregation in crumb particles) has a major effect on pore space, movement of water, and consequently on locomotion of nematodes in the soil interstices of 25–100 μm diameter. Soil structure affects decomposition and mineralization process by its effect on the grazing intensity on bacteria. Loam and clay soils have a higher bacterial biomass, but bacteria are more correlated with pores of <2 μm diameter and thus not accessible for nematodes. Grazing on bacteria by bacterivorous nematodes in grassland appeared to be higher in sandy soils than in loams and clays, resulting in a higher percentage of soil organic nitrogen (N) per day in sandy soils.^[12] In natural soils, soil particles aggregate and provide a secondary structure. Distribution of nematodes is correlated with distribution of aggregate size. Nematode grazers are found inside these aggregates where bacterial density is greater than outside aggregates.^[13] A study on the distribution of the ecto-plant-parasite *Xiphinema diversicaudatum* in an undisturbed deciduous woodland over a period of 31 years showed that the historical infestation from a bordering hedge spread into the woodland was about 30 cm/yr. Vertical distribution of PPNs depends on the rhizosphere of the host plant; ectoparasites have been found up to 2 m depth.^[14] Nematodes occur in all types of soil. Coarse-textured soils favor hatching and subsequent invasion of roots by PPNs,^[15] but heavier soils on the contrary may have the advantage of reducing damage caused by PPNs because of lower population densities.^[2] Soil characteristics change with land use. Cultivation reduces abundance of some genera of free-living nematodes such as *Diptherophora*, *Prismatolaimus*, and *Tylenchorhynchus* consistently.^[16] Sensitivity of some taxa to mechanical disturbance is exploited, e.g., to control stubby-root nematodes by reducing population densities to beyond damage threshold by plowing.^[2] Management of soilborne pathogens often occurs by the application of synthetic chemical biocides, which results in an impoverished soil fauna. Soil fumigation, e.g., decreases the microbial population and strongly reduces nematodes, resulting in soils that are only inhabitable by primary colonizers.^[16] Also, change in soil moisture regime may have an impact on the incidence of damage by PPNs. Hockland (personal communication) observed that carrots grown for processing, which require less water, showed less damage by stubby-root nematodes. Some plant ectoparasites, e.g., *Xiphinema bergeri*, show a broad tolerance and occur in habitats that are subjected to periods of drought as well as waterlogged conditions as in rice fields.^[14]

Soil pH

In experiments where soil pH was manipulated, terrestrial nematode communities reflect the disturbances caused by induced changes of soil pH.^[17] In an arable

agroecosystem, increase of soil pH had a positive effect on the total number of bacterivorous nematodes but led to a reduction of hyphal feeders. A low soil pH in combination with higher copper levels increased the toxic effect of copper and reduced the total number of nematode species.^[18] The effects of soil pH on nematode behavior differ according to the species; e.g., *Trichodorus similis* (common European virus-vector nematode) prefers more acid soils, while *Trichodorus primitivus* occurs more in neutral to alkaline soils.^[19]

Temperature

Temperature affects nematode physiological processes (rates of assimilation and respiration) and behavior and determines individual development rate and population growth.^[20] Nematodes react to t° gradients resulting in oriented movement toward or away from the preferred t° ; e.g., newly hatched juveniles of root-knot nematodes migrate to a preferred t° range in close proximity to plant roots and attractant root diffusates.^[15] Predicted climate change in response to elevated carbon dioxide (CO_2) in the atmosphere may shorten generation time of nematodes, which may increase population density and dominance of species better adapted to warm habitats at the expense of species near the edge of their geographic range.^[21] Temperature rise in subarctic sites increases the abundance of bacterial- and fungal-feeding nematodes but reduces species richness.^[22]

Nutrient Cycling

Energy and nutrient flow in terrestrial ecosystems are primarily mediated by bacteria and fungi. Bacterivorous nematodes play an important role in regulating decomposition processes; they alter microbial activity, microbial community structure, and N mineralization.^[23] Decomposition rates are sensitive to physical disturbance. Bacteria and bacterivorous nematodes regulate decay rates in incorporated residues in conventional till soils, while fungi and fungivorous nematodes are more likely to regulate decomposition of surface residues in no-till soils.^[24] Nematodes affect N availability directly by the excretion of ammonium and indirectly by freeing N immobilized by microbes through metabolism, excretion, and dispersal; they contribute between 8% and 19% of N mineralization in conventional and integrated farming systems.^[25] Health of agricultural soils can be improved by organic matter amendments and forms a critical component of sustainable agricultural production.^[23] Most genera correlate positively with the addition of organic fertilizers, but a consistent effect across multiple seasons was only observed for a few genera of free-living nematodes (*Cruzema*, *Mesorhabditis*, *Mesodorylaimus*, and *Nygolaimus*).^[16] Continued detrimental loss of organic matter in some production systems as in

intensive cotton production may reduce the resilience to plant pathogens.^[26]

Impact of Soil Biota

Plant roots attract nematodes, which show consistent directions of movement toward CO₂.^[15] Monoculture of crops (maize) led to a drop in nematode diversity and an increase in the incidence of PPNs.^[27] Suppressive soils (=soils with antipathogenic potential) possess a biological buffering against pests such as nematodes, by microorganisms (fungi, *Verticillium chlamydosporium*, or bacteria, *Pasteuria* sp.), which are primarily responsible for maintaining nematode population densities below damage threshold.^[26] In contradiction to the hypothesis of soil food web models, carnivorous nematodes are less successful in controlling root feeding nematodes than soil microorganisms.^[28,29]

Nematode Assemblages and Response to Disturbance

Soil nematode communities vary among ecosystems not only because of differences in soil characteristics but also because of differences in plant diversity such as between agricultural and natural ecosystems and in the former between annual and perennial crops. Soil communities under perennial crops more closely resemble natural ecosystems.^[30] Plants show differences in rooting patterns, which favors some species. Mobile ecto- and semi-endoparasitic nematodes, e.g., are more abundant under grasses, while sedentary ecto- and endoparasites are more common under forbs where the soil appears to be more fungal dominated.^[31]

Understanding the relationship of biodiversity to ecosystem functioning and stability is indispensable for a sustainable agriculture, environmental monitoring, and the restoration of ecosystems based on nematodes. Nematode diversity can be assessed at species, genus, or trophic level. Diversity at trophic level reflects food web complexity and is in general greater in perennial and natural systems than in annual cropping systems. Change in community composition through time reflects seasonal dynamics and ecological succession.^[24] Within a food web (Fig. 3), three energy pathways can be recognized, namely: the plant root, bacterial, and fungal pathways (Fig. 3). Primary herbivores as plant-feeding nematodes decrease the primary productivity of the plant by altering water uptake and nutrients; nutrients will become incorporated in detritus that support the bacterial and fungal pathways, which include bacterivorous and fungivorous nematodes.^[32] All three pathways unite at higher levels in the food chain with omnivorous and predatory nematodes. Secondary and tertiary consumers as omnivores feed on species in any of the trophic groups. A healthy soil ecosystem is characterized by

Fig. 3 Functional groups in a soil food web in relation to soil nutrient cycling.

Source: Modified after Ingham, Trofymow, et al.^[33]

high biodiversity and high community stability that can overcome short- or long-term disturbance and stress and is able to maintain the integrity of nutrient cycling and energy flow, suppress of pests and pathogens, and improve plant health.^[34] Insight into the functional role of nematodes in the ecosystem can be deduced from nematode feeding groups, established largely on stoma morphology. Depending on the author, five to eight main feeding types are distinguished: plant-feeding, hyphal- or fungal-feeding, bacterial-feeding, substrate ingesters, carnivores, unicellular eukaryote feeders, dispersal stages of animal parasites, and omnivores; many nematodes feed on more than one source and could be considered as omnivore.^[32] Insight into the effect of environmental disturbance (natural or anthropogenic) is revealed by changes in the nematofauna.^[26] A history of disturbance can be traced by looking at the successional status of a soil community. The early stage of succession favors the opportunistic species (colonizers) such as bacteria and their predators, small organisms with short generation time, rapid dispersal, and generalist feeding habits as in bacterivorous nematodes. This stage is generally transformed to a more diverse community with an increase in relative abundance of fungi and slower fungivorous nematodes. Secondary and tertiary consumers as predators establish later in a more stable condition. If disturbance is severe, few communities will persist. Chemical and physical disturbance are the main types of disturbance in agriculture.

To analyze the complex structure of nematode assemblages and ecological succession or disturbance, Bongers^[35]

Fig. 4 Cp triangle showing (a) shifts during eutrophication, initial situation, and 2 weeks after adding powdered cow dung; (b) artificial acidification of coniferous forest soil; and (c) recovery, 33 and 44 weeks after organic manuring.

Source: Russian Journal of Nematology, 1995.

&classified nematode genera according to their feeding type and assigned them to a colonizer (r)–persister (K) life strategy scaling or a 1–5 cp scale; cp-1 are enrichment opportunists with a short life cycle and high fecundity; cp-2 are general opportunists with a moderate life cycle and lower fecundity and are stress tolerant and considered to be part of a basal fauna present in all soils; and cp-3–cp-5 are structure indicators with a long life cycle, large body, and low fecundity and are stress intolerant (Fig. 4). Bongers developed the nematode maturity index (MI) for free-living nematodes taking feeding type and life cycle into account. Later, several adaptations of MI were made, including a separate index for PPNs or a modified MI including all soil nematodes.^[36] The MI is the weighted mean of the frequency of the taxon with corresponding cp value:

$$MI = \sum \frac{v_i \times f_i}{n}$$

where v_i = cp value assigned to taxon (family), f_i = frequency of family i in sample, and n = total number of individuals in a sample. Large values for MI point to a late successional stage with persisters (e.g., Dorylaims), while a low MI value is typical for unstable habitats with many successful colonizers such as rhabditids. To evaluate a pollution-induced stress factor, Bongers and Bongers^[37] proposed MI_{2-5} same as MI but without cp-1 group.

Other measures of ecological succession include the fungivore/bacterivore ratio (f/b ratio) as indicator of the dominant decomposition pathway;^[38] the structure index (SI) that describes whether a soil ecosystem is matured (high SI) or disturbed (low SI); the enrichment index (EI) that is based on the expected responsiveness of the opportunistic guilds (bacterivores with cp-1 or Ba1) to the increase in food, reflecting the activity of primary detritus-feeding nematodes (high EI = nutrient enriched; low EI = depleted); and the channel index that gives the percentage of fungivores among the total fungivores and

Fig. 5 A simplified food web structure showing the effect on EI and SI. Ba, bacterivore; Ca, carnivore; Fu, fungivore; Om, omnivore.

Source: Modified from Ferris, Bongers, et al.^[38] and Ferris & Bongers.^[39]

opportunistic bacterivores and describes the dominant decomposition channels in the food web.^[38] The calculation of SI and EI is based on guilds, which combines feeding type and cp value to cluster nematode taxa; they can be used to construct a faunal profile, with change in resources reflecting the succession of nematode communities from basal to enriched or to structured.^[39] Readily decomposed components are utilized fast by bacteria; more recalcitrant components are resources for fungi (Fig. 5). To obtain a well-functioning system, agricultural ecosystems may require input of organic material.

CONCLUSION

Nematodes are suitable as bio-indicators for overall soil condition because they occupy different trophic levels within soil food webs, reflect the succession stage of the system they inhabit, and show different sensitivities to toxins and stressors, such as chemicals and metals.^[40] More wide exploitation of nematode potentials as indicators for soil health is associated with technical innovations such as the use of advanced molecular tools. Time-consuming identification problems and small-scale fauna investigations will be overcome by application of next-generation sequencing on faunal assemblages or real-time polymerase chain reaction as diagnostic tool for quantification of nematodes. However, the interpretation of sequence data is not always straightforward, and the discrimination of related species for precise insight about abundance remains difficult.^[41,42] Nematode indices could become more cost-effective if they would be reduced to genera with known sensitivity or response to specific types of disturbance.^[16] Concerns on the impact of climate change are analyzed by modeling changes in

temperature, moisture, elevated CO₂, and ultraviolet B radiation. The effects of altered conditions were observed and either appeared taxon dependent^[43] for temperature and moisture or showed changes in functional groups to the latter factors.^[44]

Abstract

Despite of all efforts, soil and land degradation is increasing across sub-Saharan Africa (SSA). One reason for this is that many homes in SSA have no access to modern energy supply. Most of the energy used for cooking and heating comes from firewood, charcoal, crop residues, or even dung. Since biomass collection for energy use is not counterbalanced by soil nutrient increasing measures these habits results in significant vegetation and soil degradation, and decreasing water supply in wells and rivers. As a consequence, the provision of water, food, and energy is not ensured in many regions of SSA. The entry shows that food, energy and water security are interlinked as a Gordian knot. At the heart of these interlinkages is the Nexus of water, soil, and waste. Solutions to food and water issues in SSA must involve the establishment of land use systems which produce more food and bioenergy based on a sustainably enhanced productivity of soils and land. It is discussed that multifunctional land use systems based on agroforestry concepts meet these needs. As an innovative strategy to improve soils and land in SSA, the integration of non-food bioenergy systems across the landscape on degraded soils and on soils with medium to low productivity is suggested. It is demonstrated how the productivity of these sites could be increased by integrating waste from households and farms into the biomass production cycle. Finally, the potential impacts of implemented multifunctional land use systems on environmental, social, and socioeconomic aspects are illustrated.

INTRODUCTION

Despite all efforts, the provision of water, food, and energy is not secured in many regions across sub-Saharan Africa (SSA). For instance, one in four people suffered from malnourishment in 2013.^[1] Besides increasing variability and change in climate and the growing demand for resources, such as water, soil, and biomass, poor management of these resources is also a major part of this problem. It results, among other things, in a detrimental decline of soil and land resources.

Many households in SSA have no access to modern energy supply. Instead, traditional biomass fuel—that is, mostly firewood (unprocessed woody biomass) and charcoal—supplies over 70% of the household energy in SSA and 93% of households rely on wood fuel (as firewood, charcoal, pellets, biogas, and cellulosic ethanol) for their daily cooking.^[2] Since the extraction of biomass for energy use is not compensated by soil fertility enhancing and nutrient recycling measures, in the midterm and long term, these practices result in significant vegetation and soil degradation, nutrient depletion of soils, and decreasing water supplies in wells and rivers. As a consequence, this in turn leads to a decrease in biomass production across SSA, thus further decreasing energy supply. Due to this

close interconnectedness between food and energy issues, sub-Saharan countries will not be able to solve their food problem without solving their energy problem, and without a satisfactory solution to both, their economic growth will be severely constrained.^[3] In the following, we will elaborate coping strategies that illustrate the interlinkages between food and energy security by advancing a nexus approach toward the integrated management of soil, water, and waste.

OVEREXPLOITATION OF BIOMASS FROM FOREST AND CROPLAND

In SSA, firewood is the main energy source in rural areas whereas charcoal is the major source of household energy for the majority of the urban dwellers. Traditional firewood collection is seen as sustainable because it involves collecting dead branches and small dead trees, whereas the collection rates are usually below regeneration rate. However, dead wood collection removes nutrient from soils, and it is unknown the extent to which natural forests are impacted, and whether or not impact translates into direct effects on vegetation growth and/or species composition.^[4] In contrast to traditional firewood collection,

Fig. 1 Vicious cycle of overexploitation of biomass from forested and cropped land, concurrent degradation, downward spiral of food and fuelwood production, and decline in blue and green water pools around cities in SSA (developed based on the studies by Sitoe and Wertz-Kanounnikoff^[6] and Karlberg et al.^[11]). Blue water: fresh water in lakes, rivers, and aquifers; green water: plant available soil water; gray water: wastewater generated in households and offices.

charcoal production is based on logging and requires land clearing. Studies from Ethiopia,^[5] Mozambique,^[6] and additional countries in SSA show localized deforestation around large cities.^[7] But charcoal production is not the primary driver of deforestation around cities. It is assumed that peri-urban zones in which charcoal production for urban dwellers can be expected to be concentrated in the beginning of urban growth are likely to be areas that are also under pressure from clearance for agriculture. Meaning, the areas from which wood for charcoal production are often sourced are also the areas that are cleared anyway.

Research has shown that there are depletion hotspots in SSA where wood fuel harvest is unsustainable.^[8] The largest hotspot, rather a huge contiguous degradation area, occurs in East Africa, extending from Eritrea through western Ethiopia, Kenya, Uganda, Rwanda, and Burundi and affecting 26% of the region's population. Smaller hotspots can be found in western and southern Africa (e.g., in Lesotho or in southern Mozambique). In these hotspots, biomass scarcity is prevalent and many farmers are using crop residues or cattle dung instead of wood fuel as energy source for cooking and heating.^[9,10]

Fig. 1 illustrates how that periodic removal of organic matter and nutrients and the misuse of dung for cooking and heating instead of fertilization gradually lower soil fertility

and thus soil productivity and ultimately food security. These habits result in a self-propagating, vicious cycle of overexploitation of biomass from forested and cropped land, concurrent degradation, and downward spiral of food production.^[11] This leads to high risks with regard to achieving and sustaining food security by constituting major biophysical limitations for agricultural production in SSA.^[12] It is projected that SSA's population will double to 2.4 billion by 2050, as a result, the demand for food and fuelwood can also be expected to increase significantly.^[13] Moreover, urbanization will further exacerbate the pressure on rural and peri-urban zones around the cities; in 2014, SSA's urbanization level was 37%, and by 2050, 54% of SSA's population is projected to live in urban areas. In the absence of affordable alternatives, bioenergy use—in particular charcoal—is expected to increase significantly over the next decades.^[14] It is estimated that for each 1% in urbanization, there will be a 14% increase in charcoal use.^[15]

The problem of securing food and energy for an ever growing urban population is inextricably linked to forest and cropland degradation in the hinterland of SSA's cities. But this degradation is also associated with change in soil properties relevant for the partition of rainfall into surface and subsurface water. How much water infiltrates,

evaporates, or leaks depends not only on vegetation and climate but also on the geometry of the soil pore space and therefore on soil structure. The latter is strongly related to permeability and water storage capacity of soils; it is well known that changes in land cover and available nutrient pools can induce the loss of soil structure and hence modify soil properties relevant for transmission and storage of water. As a consequence, the decline in forests and cropland favors increased surface runoff transporting excess soil into surface water and inducing silting and eutrophication of these (i.e., a decline in blue water pools; Fig. 1).

The lack of vegetated soil surfaces also leads to excess water erosion, which in turn reduces the infiltration rate of rainwater into the soil and lowers soil water pools available for plant growth (i.e., decline in green water pools). The decline in blue and green water pools due to the combination of contaminated surface waters and reduced infiltration of rainfall into the soil further promotes increased withdrawals for agricultural, domestic, and industrial use. Withdrawals often end up exceeding recharge rates, thus resulting in a decline in available blue-water pools. In the long run, these practices are not sustainable.

INTEGRATING ORGANIC WASTES INTO THE BIOMASS PRODUCTION CYCLE

It has been proposed to substitute traditional wood fuel with renewable energy from wind and sunlight,^[11] but the quick implementation of such technology is challenging.^[16] Another alternative could be biofuel made from short rotation forests, but its production would compete with food production for limited soil and water resources.^[17,18] Growing biofuel crops on marginal soils has been suggested as a way out of this dilemma. But examples across SSA have shown that water and nutrient shortage limit the yield of biofuel crops on such soils.^[19,20]

A sustainable solution to produce economically viable biofuel yields from marginal soils would be to integrate nutrients and water from organic waste (sewage sludge, compost, wastewater, etc.) into the biomass production cycle. There are promising examples from all over the world that illustrate how the application of organic waste can increase growth and yield, for instance in forest plantations.^[21] Municipalities in Sweden and Estonia are using pretreated wastewater, sewage sludge, and methanogenic landfill leachate in short rotation energy forests.^[22,23] Application of organic waste in energy forests is not just a cost-effective method to purify municipal wastewater and to produce bioenergy but also generates additional environmental benefits, such as soil carbon accumulation.^[23] This may directly translate into higher soil productivity and improved soil structure.

Much like the agricultural sector, SSA's wastewater management sector is facing challenges due to changes in

demography. The problem arises of how to deal with the ever increasing volume of wastewater in light of ineffective wastewater management, which covers only a small portion of the total wastewater volume generated. The largest part of SSA's wastewater flows into bodies of water and the environment more or less untreated. As using wastewater as a resource in food and bioenergy production may overcome some of the challenges farmers face, wastewater could be used where available. The safe use of wastewater for biomass production would also decrease the pollution of bodies of water used for irrigation. A typical example of the water–soil–waste nexus, this informal irrigation sector along streams and rivers is usually unregulated and unmonitored.

MANAGEMENT OF THE INTERLINKAGES BETWEEN FOOD, WATER, AND ENERGY SECURITY

SSA's food problem cannot be solved without solving its energy problem. Thus, the real challenge is how to manage the interlinkages. At the heart of this challenge is the nexus of water, soil, and waste (Fig. 2).

Use and alterations of one of these resources have a direct impact on the other resources. An interconnected management of soil, water, and waste is therefore an approach to ensure a sustainable intensification of biomass production. Such a strategy includes soil as well as blue and green water conservation; use of treated gray water as a source for irrigation and fertilizing; use of crop and animal waste for enhancing soil quality, preventing soil erosion, and minimizing unproductive evaporation by mulching and crop residue management; and the reuse and recycling of by-products.

Moreover, solutions to food and energy issues in SSA must involve the establishment of land use systems that produce more food and bioenergy based on a sustainable increased productivity of soils and land. Multifunctional land use systems developed according to agroforestry concepts, meet these needs. Agroforestry can play an important role in addressing the crisis of food security and environmental resilience, for instance by integrating fertilizer trees into food crop agriculture or by soil conservation hedgerows. In this context, multifunctionality can be either addressed through a single land use type, such as multifunctional agriculture, or by integrating several land uses on one piece of land (e.g., agroforestry). Similarly, from a broader perspective, landscapes that consist of a set of different spatial units (land use types) can also have spatial multifunctionality, depending on the functions of each piece of land. Such multifunctional landscapes will not only provide multiple goods and services to meet local demands but also satisfy the social needs of other areas (e.g., downstream), while the environmental resources are maintained and improved.

Fig. 2 Conceptual framework for the management of the interlinkages between food, water, and energy security.

An example for multifunctionality is to integrate bioenergy systems across the landscape on degraded soils and on soils with medium to low productivity. The productivity of these sites would then be increased by integrating organic waste (notably wastewater) from households and farms into the biomass production cycle. To this end, the concept of wastewater sanitation and reuse must be combined with multifunctional land use systems for the production of food and energy crops. In this approach, wastewater is treated in a target-oriented manner to be used for irrigation and nutrient supply of the respective land uses, considering hygienic as well as environmental aspects. Treating wastewater in this way can be cost-effective and reduces the demand for freshwater and fertilizers. Moreover, with the strategy to integrate bioenergy systems across landscapes direct and indirect effects on soils and land can be expected in the long run—direct enhancement of soil fertility at sites where bioenergy crops and improved farming systems will be established and indirect enhancement of soils and land at the landscape level because of regeneration of soils and land by reducing exploitation (firewood collection and tree logging will be significantly reduced). Other benefits of the integration of bioenergy systems across the landscape are the establishment of healthier ecosystems with better resilience to climate change and improved provision of water-related ecosystem services. Socioeconomic benefits include locally added

value, the creation of new jobs. Finally, the establishment of bioenergy crop production as part of multifunctional land use systems promotes the use of energy saving and advanced technology for electricity generation at the household and community level with social and economic benefits for households and local enterprise development.

CONCLUSION

The previous discussions revealed a major dilemma in biomass production and use in SSA: more and more food, feed, fiber, and wood for more and more people are needed, but less and less adequate soil and water resources are available. Therefore, a different approach to thinking about increased food and bioenergy production is necessary. This can be achieved, on one hand, by integrating organic waste from households and farms into the biomass production cycle and, on the other hand, by integrating bioenergy production in multifunctional land use systems. In these land use systems, the bioenergy production on degraded soils or of soils with low to medium productivity is combined with soil fertility enhancing measures, such as wastewater application. However, a successful implementation of such a concept requires the estimation of its economic feasibility and an assessment of its social acceptability. Finally, it needs to be investigated what

policy tools are necessary to reconcile competing resource uses (water, soil/land, and waste) and users. Then, the full consideration of social and environmental aspects can be considered when the concept of organic waste application is combined with multifunctional land use for the production of food and bioenergy crops or multi-purpose crops.

Soil Plant Nutrient Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Fort Collins, Colorado, U.S.A.

Abstract

The Nitrate Leaching Index is a rapid assessment tool that evaluates nitrate (NO_3) leaching potential based on basic soil and climate information. It is the basis for many nutrient management planning efforts, but it has considerable limitations because of: 1) an oversimplification of the processes affecting NO_3 leaching; and 2) a lack of management considerations.

INTRODUCTION

Nitrogen (N) is an essential plant nutrient and the key to the sustainability and economical viability of agricultural systems.^[1] On average, N use efficiencies are being reported to be about 50%, and the economic worldwide average N losses are equivalent to millions of U.S. dollars. The Environmental Protection Agency considers water with over 10 mg nitrate–nitrogen ($\text{NO}_3\text{--N}$) L^{-1} concentration unsafe for drinking purposes,^[2] and several studies have shown that NO_3 leaching from agricultural systems can readily cause this level to be exceeded.^[3,4] The Nitrate Leaching Index (NLI) is an indicator of the potential for NO_3 to reach shallow groundwater and incorporates information on soils and precipitation.^[5] It can be used as a tool to identify land areas where good N management is critical. This entry discusses the processes affecting NO_3 leaching in soils, explains the NLI and its strengths and weaknesses, and provides suggestions for improvement.

PROCESSES

The pathways of N losses need to be viewed within the context of the N cycle and the need to budget all N sources.^[6] N can readily be transformed from organic forms and ammonia fertilizer forms into $\text{NO}_3\text{--N}$, which is mobile in soil and therefore subject to leaching. However, plants require most N to be in the NO_3 form; therefore, the main objective of good agricultural N management is to have sufficient $\text{NO}_3\text{--N}$ available in the root zone for adequate plant nutrition but to avoid any excess N that would lead to high leaching losses. This is a challenge in many crop production systems because: 1) soil by its very nature is “leaky” and water percolation and leaching of chemical

substances is often unavoidable; 2) N additions cannot always be precisely managed, especially when dealing with organic sources; and 3) soil N is subject to other loss pathways such as denitrification and subsequent gaseous emission, ammonia volatilization, surface runoff, and erosion. These processes are often difficult to predict because they are affected by site-specific factors (e.g., fine-textured soils experience more denitrification than coarse-textured ones^[7]) and are strongly dependent on spurious climate factors such as temperature and precipitation. Improved management of N requires an understanding of these processes within the context of the N cycle^[6] and a recognition that inadequate predictability of the various loss pathways often causes farmers to use excess (insurance) N rates to avoid plant N deficiencies under worst-case scenarios. Nevertheless, agricultural N can be effectively managed to reduce $\text{NO}_3\text{--N}$ leaching,^[8] and the NLI is a tool developed for this purpose. We will discuss the available tool and its applications, as well as possible future improvements.

THE NLI

The extent of soil water percolation and thereby $\text{NO}_3\text{--N}$ leaching *potential* mostly depends on permeability, pore-size distribution, soil depth to a restrictive layer, artificial drainage, and precipitation amount and distribution over the year. For a given precipitation pattern, well-drained soils generally have greater N leaching potential than poorly drained soils. The NLI estimates this percolation potential from the Natural Resources Conservation Service soil hydrologic unit designations, which range from Group A soils with high percolation rates (generally coarse-textured and well-drained soils) to Group D soils with low percolation rates (generally fine-textured and poorly

drained soils). The NLI is an indicator of the potential for NO_3 to reach shallow groundwater and incorporates information on soils and precipitation as follows:^[5]

$$\text{NLI} = \text{percolation index} \times \text{seasonal index} \quad (1)$$

The percolation index (PI) is a function of the annual average precipitation (P_A , in inches) and soil hydrologic group and is estimated by the following equations for each of the hydrologic groups:^[9]

$$\text{Hydrologic Group A: } \text{PI} = (P_A - 10.28)^2 / (P_A + 15.43)$$

$$\text{Hydrologic Group B: } \text{PI} = (P_A - 15.05)^2 / (P_A + 22.57)$$

$$\text{Hydrologic Group C: } \text{PI} = (P_A - 19.53)^2 / (P_A + 29.29)$$

$$\text{Hydrologic Group D: } \text{PI} = (P_A - 22.67)^2 / (P_A + 34.00) \quad (2)$$

Soils with mixed hydrologic grouping, e.g., B/D, as a result of artificial drainage, generally use the higher percolation potential in the NLI assessment. The seasonal index (SI) is determined by the annual precipitation (P_A) and the sum of the non-growing season precipitation (typically the winter period in the United States, P_N in inches)

$$\text{SI} = (2 \times P_N / P_A)^{1/3} \quad (3)$$

The SI reflects the fact that most water percolation occurs from precipitation after crop senescence and removal, as a result of the consequent drop in transpiration rate. NLI values are generally interpreted as follows

$\text{NLI} < 2$: Low nitrate leaching risk

$2 < \text{NLI} < 10$: Medium nitrate leaching risk

$\text{NLI} > 10$: High nitrate leaching risk

Despite its simplicity, the NLI is generally effective in identifying high-leaching scenarios from low-leaching scenarios^[10] and has been widely adopted in the United States for nutrient management planning on farms.

FRAMEWORK FOR AN IMPROVED NLI

Although the NLI allows for the assessment of NO_3 -N leaching potential, it also has significant limitations because of its oversimplification of complex processes.^[11] The NLI does not actually estimate the leaching of NO_3 -N and therefore cannot be directly tied to an enforceable water-quality standard (e.g., $10 \text{ mg L}^{-1} \text{ NO}_3$ -N). The index also ignores important processes that affect N leaching, such as denitrification, which is especially significant in fine-textured soils.^[4] van Es et al.^[10] concluded that despite this shortcoming, the NLI still effectively identifies soil and climate regions of high and low leaching potential.

Another major limitation of the NLI is the lack of a connection with management practices, such as N application rates and timing, crop type, and crop rotations, which greatly influence NO_3 -N leaching. This concern has, in some cases, been addressed by providing specific management guidelines for fields with high NLI values, such as conservative N applications, optimum timing of applications, cover cropping, etc.^[10]

Shaffer and Delgado^[11] proposed a framework for an improved NLI through a *technologically based index* that requires the integration of databases describing soil hydraulic properties, climate, off-site factors and management, the use of simulation models, and the Internet. This NLI is proposed to use a dynamic ranking system similar to that for the PI,^[12] which can facilitate a preliminary assessment by classifying combinations of management scenarios, soil conditions, climate, crop types and off-site factors into leaching potential ratings. This NLI should be simple enough that it can be used by consultants, agronomists, conservationists, farmers, and technical personnel. It is proposed to have a tiered approach, where initial efforts involve simple screening to separate the higher NO_3 -N leaching potential scenarios from the lower ones.^[11] Higher tiers of this NLI should be capable of assessing N leaching potential within the context of more complex N dynamics, transformations, and mobility in the root zone. Also, this NLI must be developed so it can be simultaneously used with the PI to perform integrated analyses of nutrient loss potential, which allows for the evaluation of environmental trade-offs associated with management practices. For example, early fall manure application in the cool temperate regions of the United States is often optimal for avoiding phosphorus runoff losses but poses high N leaching risk compared to other seasonal application periods.^[10]

At the first tier of application, the NLI should be simple enough to be applied across large regions. At the higher, more complex levels, the NLI should be capable of evaluating the leaching potential related to site-specific management scenarios by being coupled to geographic information system and capable of identifying variable NO_3 -N leaching areas across single fields of various soil characteristics and management scenarios. A final attribute of a new NLI should be its national scope and consistency but not necessarily identical formulation. This allows for uniform standards and effective communication among technical service providers and scientists.^[11]

A new NLI needs to be developed with mechanistic dynamic simulation models (e.g., GPFARM, EPIC, LEACHM, NLEAP, GLEAMS, and RZWQM) that can account for the complex N pathways, transformations, and interactions with other nutrients.^[13] This is especially important for the evaluation of cases where organic N sources are being applied to the fields, which are generally of the greatest concern with nutrient losses.

CONCLUSION

The NLI is a rapid assessment tool that evaluates N leaching potential based on basic soil and climate information. It is the basis for many nutrient management planning efforts but has considerable limitations because of: 1) an oversimplification of the processes affecting N leaching and 2) a lack of management considerations. Improved N management in the landscape requires a new NLI that considers the complex interactions of climate conditions, soil characteristics, crop type, off-site factors, and management scenarios. A tiered approach is proposed to achieve these multiple objectives.^[11]

Abstract

Nitrate (NO_3) leaching is a significant nitrogen (N) loss process for agriculture that must be managed to minimize NO_3 enrichment of groundwater and surface waters. Managing NO_3 leaching should involve the application of basic principles of understanding the site's hydrologic cycle, avoiding excess rates of N, and applying N in phase with crop demand. Other specific techniques to reduce NO_3 leaching are presented in this entry.

INTRODUCTION

Nitrate leaching occurs when the soil nitrate–nitrogen ($\text{NO}_3\text{--N}$) concentrations are high and water moves beyond the root zone. Leaching losses in modern agriculture commonly account for 10–30% of the N additions.^[1–3] Leaching can contribute to NO_3 enrichment of groundwater, which has a health advisory limit of 10 mg $\text{NO}_3\text{--N/L}$, and to the eutrophication of surface waters that can lead to the development of hypoxic zones in receiving waters. Managing leaching requires development of site-specific practices that should be based on an understanding of the soil–crop–hydrologic cycle, avoiding excess N by applying a N rate to meet expected yields, and applying N in phase with crop demand. Specific NO_3 management approaches include adjusting irrigation inputs according to site water needs, employing cropping systems that fully utilize soil–water resources, and utilizing within-season and real-time N monitoring tools. The goal of this entry is to discuss practical techniques to reduce NO_3 leaching from modern agriculture.

APPROACHES FOR DECREASING NO_3 LEACHING

Primary Techniques for Managing NO_3 Leaching

The major NO_3 leaching management techniques include understanding the soil–crop–hydrologic cycle, applying the proper rate of N, and applying N in phase with crop demand. Because water movement is the driving force for

NO_3 leaching, it is essential to understand the hydrologic cycle before developing site-specific leaching management strategies.^[1] Understanding the hydrologic cycle of the site should identify the most likely times when leaching can occur, i.e., the times when the soil is at near field capacity and water inputs exceed water use by evapotranspiration (ET). In humid regions, leaching is usually minimal in summer when ET exceeds precipitation. But during the winter-to-spring season, precipitation exceeds ET and leaching is common, as shown by the percolate data of Fig. 1, adapted from large monolith lysimeter data from Ohio, U.S.A.^[3] In irrigated agriculture, leaching is most likely to occur during the growing season from excess water inputs on coarse-textured soils. Controlling leaching in humid regions should focus on management practices to keep the soil $\text{NO}_3\text{--N}$ levels low during the fall season and on providing a crop N sink during the non-growing season, such as a grass cover crop. In irrigated agriculture, avoiding excess irrigation inputs through irrigation scheduling is an effective method to manage leaching.

Avoiding excess N inputs, from fertilizer and/or manure, is the most fundamental approach to control leaching because crop N use efficiency is usually high for plants responding to N. By contrast, N rates on the non-responsive part of the yield curve are associated with lower efficiencies and high levels of unused N that is vulnerable to leaching. The data of wheat grain N removals (assuming 20 kg N/t grain) from the Rothamsted Broadbalk Study are summarized in Fig. 2; the associated estimate of N leaching is adapted from the study by Gouldings.^[4] These data show only small leaching losses for N rates in the responsive part

Fig. 1 Monthly lysimeter percolate (upper panel) and N leached (lower panel, as percent of total yearly N leached) for large monolith lysimeters in Coshocton, Ohio, U.S.A.

Source: From Chichester & Smith.^[3]

of the curve, with a marked increase in leaching in the non-responsive portion of the curve (Fig. 2). Applying the proper N rate usually involves estimating the crop N need from the expected yield and then subtracting N credits from residual $\text{NO}_3\text{-N}$, irrigation N inputs, prior legume crop credits, and adjusting for available manure N.^[1]

Applying N in phase with crop demand is also a fundamental approach for managing leaching that involves applying N after crop establishment, or after each forage harvest in grass-forage systems. Timing N applications to closely match crop N uptake minimizes the time that N is exposed to uncontrolled rainfall inputs and thus leads to lower leaching losses.

Irrigation and Cropping System Techniques for Managing NO_3 Leaching

Other NO_3 management techniques include irrigation scheduling, modifying the cropping system, and developing

Fig. 2 Wheat grain N yield and N leaching for various fertilizer rates; Broadbalk Study, Rothamsted, U.K.

Source: From Gouldings.^[4]

riparian zones and conservation acres. Irrigation water management techniques are based on irrigation scheduling, which adds irrigation in accordance with ET and soil-water status. Irrigation scheduling can reduce leaching by avoiding excess water applications, by adjusting water inputs to local weather, and by adding water based on local soil properties and local soil-water content. For example, irrigating at 85% of ET, compared to 100% of ET, reduced leaching losses from about 110 to 60 kg N/ha on a sandy soil in Nebraska, U.S.A.^[5] Similarly, Diez et al.^[6] reported that scheduled irrigations to account for crop water demands can reduce the leaching of water and of $\text{NO}_3\text{-N}$ by 4 times, compared to excess irrigation. Meisinger and Delgado^[1] summarized cropping system effects on leaching and concluded that adding a grain legume, such as soybeans, can partially reduce leaching compared to continuous corn (typically 5–10%), but adding a forage crop, such as alfalfa or a forage grass, can substantially reduce leaching (typically 70–90%). However, changing the cropping system requires simultaneous changes in marketing and/or livestock enterprises. Delgado^[7] reported that cropping systems that have shallow-rooted crops and are heavily fertilized are most susceptible to $\text{NO}_3\text{-N}$ leaching. However, N recovery can be significantly improved by adding a deep-rooted crop such as malting barley. The barley served as a scavenger crop and even mined $\text{NO}_3\text{-N}$ from the system.^[7]

Adding a grass cover crop is another cropping system approach to reduce leaching by converting mobile $\text{NO}_3\text{-N}$ to immobile plant protein. A review of the effects of cover crops on water quality^[8] concluded that grass covers can reduce NO_3 leaching by an average of 70% compared to no-cover, while legume covers can reduce leaching by about 20%. Cover crops are especially useful in humid regions, where the winter leaching potential is high (Fig. 1). Developing riparian zones and conservation reserve areas can reduce the N loss from production fields into adjacent streams, especially in tile-drained watersheds.^[1]

Other Approaches for Managing NO_3 Leaching

Meisinger and Delgado^[1] have also discussed other leaching management techniques. Nitrification inhibitors can delay leaching losses but are most effective in conjunction with other techniques, such as reduced N rates. Changing tillage practices usually have only secondary effects on leaching. Drainage-ditch water control measures can reduce NO_3 transport to streams by impounding water and promoting denitrification but have limited geographic applicability. Improved N application equipment is a direct approach to improve N application accuracy and avoiding excess N rates; new application equipment can apply N at the meter and submeter spatial scale.

Within-Season Monitoring Techniques for Managing NO₃ Leaching

In-season testing and real-time sensors are tools developed for managing leaching. These monitoring approaches seek to identify N sufficient or deficient areas within a field and adjust subsequent N applications accordingly. The leaf chlorophyll meter (LCM) compares leaf greenness to the LCM reading in a well-fertilized reference strip. The relative LCM value has been shown to successfully predict the need for extra fertilizer N, especially in irrigated systems where N can be applied with irrigation water.^[9] The pre-sidedress soil nitrate test (PSNT) measures NO₃-N in the surface 30 cm of soil when corn is about 30 cm tall and compares it to a sufficiency concentration of 20–25 mg NO₃-N/kg. The PSNT is the most useful for diagnosing N sufficient sites. A study^[10] carried out in Connecticut, U. S.A., compared conventional N management with the PSNT and reported N leaching losses of 50 and 20 kg N/ha, respectively. Plant stem or petiole NO₃-N tests measure plant NO₃-N sufficiency at specific growth stages and are commonly used in vegetable crops.^[1]

Real-time sensors that measure crop biomass and greenness based on remotely sensed or tractor-mounted units sense red and near infrared reflectance^[11] and are new tools for managing N leaching. Data from real-time sensors have a meter to submeter resolution and can be combined with geographically mapped data of soil properties and previous crop yields to produce a real-time assessment of N status, potential yield, and the suggested N application based on crop simulation models such as nitrate leaching and economic analysis package.^[7] These above seasonal and real-time monitors have been shown to reduce NO₃ leaching by identifying N sufficient areas and avoiding the applications of excess N; they can also increase profitability by identifying N deficient areas with excellent small-scale resolution. An example of the benefits from Precision Agriculture has been reported by Bausch and Delgado^[11] who reported that using geographic information system (GIS) and remote sensing tools for in-season N management resulted in N applications that required 52% less N than that used under conventional practices (214 kg N/ha/yr). On average, the in-season N management saved 102 kg N/ha/yr which was worth about \$55/ha/yr, without yield reductions during two consecutive growing seasons. These results show that precision management can significantly improve N efficiency of corn systems without reducing grain yields, thus minimizing the potential for NO₃-N leaching.

CONCLUSION

NO₃ leaching is a significant N loss process for agriculture that must be managed to minimize NO₃ enrichment of groundwater and surface waters. Managing NO₃ leaching

should involve the application of basic principles of understanding the site's hydrologic cycle, avoiding excess rates of N, and applying N in phase with crop demand. Other specific techniques to reduce leaching include use of irrigation scheduling, grass cover crops, within-season monitoring with soil NO₃-N tests or LCMs, real-time sensors using red and near infrared reflectance, and use of remote sensing with GISs and simulation models to identify the best combination of practices to control leaching. The application of a specific combination of the above practices should increase crop N recovery with concomitant reductions in NO₃-N leaching.

Nitrogen and its Transformations

Oswald Van Cleemput

Pascal Boeckx

Faculty of Agricultural and Applied Biological Sciences, University of Ghent,
Ghent, Belgium

Abstract

Nitrogen (N) is essential to all life. It is the nutrient that most often limits biological activity. In agricultural and natural ecosystems, N occurs in many forms covering a range of valence states from -3 to $+5$. The change from one valence state to another depends primarily on environmental conditions. The transformations and flow from one form to another constitute the basics of the soil N cycle. The use of N fertilizers has become essential to increase the productivity of agriculture and has resulted in an almost doubling of the global food production. However, this also implies that the natural N cycle has substantially been disturbed. In the following sections, an overview of the different N transformation processes in the soil is given.

THE NITROGEN (N) CYCLE: GENERAL

Atmospheric nitrogen gas (N_2 ; valence 0) can be converted by lightening to various oxides and finally to nitrate (NO_3^- ; valence $+5$), which can be deposited and taken up by growing plants (Fig. 1). Also N_2 can be converted to ammonia (NH_3 ; valence -3) by biological N_2 fixation, with the NH_3 participating in a number of biochemical reactions in the plant. When plant residues decompose, the N compounds undergo a series of microbial conversions (mineralization), leading first to the formation of ammonium (NH_4^+ ; valence -3) and possibly ending up in NO_3^- (nitrification). Under anaerobic conditions, NO_3^- can be converted to various N oxides and finally to N_2 (denitrification). When mineral or organic N fertilizers are used, they also undergo the same transformation processes and influence the rate of other N transformations. In considering the soil compartment, there can be N gains (such as biological N_2 fixation) as well as N losses (such as leaching and denitrification). Furthermore, N can be exported from the soil via harvest products or immobilized in soil organic matter.

N TRANSFORMATIONS IN THE SOIL

The principal forms of N in the soil are NH_4^+ , NO_3^- , or organic N substances. At any moment, inorganic N in the soil is only a small fraction of the total soil N. Most of the N in a surface soil is present as organic N. It consists of proteins (20–40%), amino sugars, such as the hexosamines (5–10%), purine and pyrimidine derivatives (1% or less), and complex unidentified compounds formed by the reaction of NH_4^+ with lignin, polymerization of quinones with

N compounds, and condensation of sugars and amines. In the subsoil, an important fraction of the present N can be trapped in clay lattices (especially *illitic* clays) as non-exchangeable NH_4^+ and is consequently largely unavailable. Organic substances slowly mineralize by microorganisms to NH_4^+ , which could be converted by other microorganisms to NO_3^- (see further).

The NH_4^+ can be adsorbed to negatively charged sites of clay minerals and organic compounds. This reduces its mobility in the soil compared to the more mobile NO_3^- ion.

Microorganisms can use both NH_4^+ and NO_3^- to satisfy their need for N. This type of N transformation is called microbial immobilization.

The ratio between carbon (C) and N (C/N ratio) in organic matter determines whether immobilization or mineralization is likely to occur. When utilizing organic matter with a low N content, the microorganisms need additional N, decreasing the mineral N pool of the soil. Thus, the incorporation of organic matter with a high C/N ratio (e.g., cereal straw) results in immobilization. The incorporation of organic matter with a low C/N ratio (e.g., vegetable or legume residues) results in N mineralization. A value of the C/N ratio of 25–30 is often taken as the critical point toward either immobilization or mineralization.

Nitrification is a two-step process. In the first step, NH_4^+ is converted to nitrite (NO_2^- ; valence $+3$) by a group of obligate autotrophic bacteria known as *Nitrosomonas* species. The second step is carried out by another group of obligate autotrophic bacteria known as *Nitrobacter* species. Also a few heterotrophs can carry out nitrification, usually at much lower rates.

Soil water and aeration are crucial factors for nitrification. At a water potential of 0 kPa (saturation), there is little air in the soil and nitrification stops, due to oxygen

Fig. 1 The soil N cycle. The white compartment represents the atmosphere, the light gray compartment represents the biosphere, and the dark gray compartment represents the subsoil.

limitation; nitrification is greatest near field capacity (−33 kPa in medium- to heavy-textured soils to 0 to −10 kPa in light sandy soils). Also in dry soils, NH_4^+ and sometimes NO_2^- accumulate presumably because *Nitrobacter* species are more sensitive to water stress than the other microorganisms.

Nitrification is slow in acid conditions with an increasing rate at increasing pH. Mainly under alkaline conditions, NO_2^- is also accumulating, because *Nitrobacter* is known to be inhibited by NH_3 , which is formed under alkaline conditions. Nitrification is a process that acidifies the soil as protons (H^+) are liberated as follows:

During nitrification, minor amounts of nitrous oxide (N_2O ; valence +1) and nitric oxide (NO ; valence +2) are formed. Both compounds have environmental consequences, as discussed below.

The effect of temperature on nitrification is climate dependent. There is a climatic selection of species of nitrifiers, with those from cooler regions having lower temperature optima and less heat tolerance than species from warmer regions. All abovementioned factors influencing nitrification also influence the nitrifying population. The population and activity of nitrifiers can be reduced by the use of nitrification inhibitors, such as dicyanodiamide,

nitrapyrin, and neem (*Azadirachta indica*) seed cake. They are used mostly to retard the nitrification of manure; otherwise, their practicality is controversial, and they are not extensively used. More details about nitrification and nitrification inhibitors can be found in the studies by McCarty^[1] and Prosser.^[2]

N INPUT PROCESSES

Atmospheric N Deposition

The total atmospheric N (NH_4^+ and NO_3^-) deposition is in the order of 10–40 kg N ha^{−1} yr^{−1} in much of north-western and Central Europe and some regions in North America. It ranges from 3 to 5 kg N ha^{−1} yr^{−1} in pristine areas.^[3] It is originating from previously emitted NH_3 and NO_x from agricultural and industrial activities or traffic.

Biological N Fixation

Rhizobium species living in symbiotic relationship in root nodules of legumes—e.g., clover (*Trifolium*), lucerne (*Medicago*), peas (*Pisum*), and beans (*Faba*)—can convert atmospheric N_2 to NH_3 , which is further converted to amino acids and proteins. Parallel to this process, the *rhizobium* species receive from the legume the energy they

need to grow and to fix N_2 . Photosynthetic cyanobacteria are also N-fixing organisms and are especially important in paddy rice (*Oryza*). The amount of N fixed varies greatly from crop to crop, ranging from a few $kg\ N\ ha^{-1}\ yr^{-1}$ to a few hundred $kg\ N\ ha^{-1}\ yr^{-1}$. The process is depressed by ample N supply from other sources, and it is sensitive to the lack of phosphorus. The amount of globally fixed N is almost double the amount of applied fertilizer N. Next to symbiotic N-fixing bacteria, also non-symbiotic species (e.g., *Azotobacter*) occur in soils. In general, free-living diazotrophs make a small but significant contribution to the soil N status. Some non-leguminous trees and plants [e.g., alder (*Alnus*) and sugarcane (*Saccharum*)] host N-fixing bacteria as well. Much uncertainty exists about the association of N-fixing bacteria with nonlegumes (the so-called associative N-fixing bacteria).

Mineral and Organic N Fertilization

Theoretically, plants should prefer NH_4^+ to NO_3^- because NH_4^+ does not need to be reduced before incorporation into the plant. In most well-drained soils, the oxidation of NH_4^+ is fairly rapid, and therefore, most plants have developed to grow better with NO_3^- . However, a number of studies have shown that plants better develop when both sources are available. Rice, growing under submerged conditions, must grow in the presence of NH_4^+ , as NO_3^- is not stable under flooded conditions. When urea is applied, it rapidly hydrolyzes under well-drained conditions, unless a urease inhibitor is being added; under submerged conditions, rice plants may also absorb N directly as molecular urea. Organic manure can be of plant or animal origin or a mixture of both. However, most comes from dung and urine from farm animals. It exists as farmyard or stable manure, urine, slurry, or compost. Because its composition is not constant and because plant material (catch or cover crops and legumes) is often added freshly (green manure) to the soil, less than 30% of its nutrients becomes available for the next crop.

N UPTAKE BY PLANTS

Growing plants get their N from fertilizer N as well as from organic soil N upon mineralization. Plants take up N compounds both as NO_3^- and as NH_4^+ . In general, NO_3^- is the major source of plant N. There is some evidence that small amounts of organic N (urea or amino acids) can be taken up by plants from the soils solution. Plant uptake of N can be studied through the use of mineral fertilizers or organic matter labeled with the stable N isotope ^{15}N . The proportion of applied N taken up by the crop is affected by many factors, including crop species, climate, and soil conditions. Aboveground

parts of the crop can recover 40–60% of the fertilizer N applied.

N LOSS PROCESSES

NH_3 Volatilization

Losses of N from the soil by NH_3 volatilization amount globally to 54 Mt (or $10^{12}\ g\ NH_3-N\ yr^{-1}$), and 75% is of anthropogenic origin.^[4] According to the European Centre for Ecotoxicology and Toxicology of Chemicals,^[5] the dominant source is animal manure, and about 30% of N in urine and dung is lost as NH_3 . The other major source is surface application of urea or NH_4^+ bicarbonate and to a lesser degree other NH_4^+ -containing fertilizers. As urea is the most important N fertilizer in the world, it may lead to important NH_3 loss upon hydrolysis and subsequent pH rise in the vicinity of the urea till. The transformation of NH_4^+ to the volatile form NH_3 increases with increasing pH, temperature, soil porosity, and wind speed at the soil surface. It decreases with increasing water content and rainfall events following the application. NH_3 losses from soils can be effectively reduced by fertilizer incorporation or injection instead of surface application.

Emission of N Oxides (N_2O and NO) and Molecular N (Nitrification and Denitrification)

Microbial nitrification and denitrification are responsible for the emission of NO and N_2O .^[6] They are by-products in nitrification and intermediates during denitrification. Probably about 0.5% of fertilizer N applied is emitted as NO ^[7] and 1.25% as N_2O .^[8] However, wide ranges have been reported. The intensification of arable agriculture and of animal husbandry has made more N available in the soil N cycle increasing the emission of N oxides. The relative percentage of NO and N_2O formation very much depends on the moisture content of the soil. At a water-filled pore space (WFPS; or the fraction of total soil pore space filled with water) below 40%, NO is produced mainly from nitrification. Between a WFPS of 40% and 60%, the formation of NO and N_2O from nitrification occurs. Between a WFPS of 60% and 80%, N_2O is predominantly produced from denitrification, and the formation of NO is decreasing sharply. At a WFPS above 80%, the formation of N_2 by denitrification is dominant. In practice, these WFPS ranges will overlap and depend on the soil type.^[9] Next to water content, also temperature, land use, availability of N, and decomposable organic matter are important determining factors for N_2O formation. N_2O is a greenhouse gas contributing 5–6% to the enhanced greenhouse effect. Increased concentrations are also detrimental for the stratospheric ozone layer.^[10] In the presence of sunlight, NO_x (NO and NO_2) react with volatile organic compounds from evaporated petrol and solvents and from vegetation and

forms tropospheric ozone, which is, even at low concentration, harmful to plants and human beings. The major gaseous end product of denitrification is N_2 . The ratio of N_2O to N_2 produced by denitrification depends on many environmental conditions. Generally, the more anaerobic the environment, the greater the N_2 production. Denitrification is controlled by three primary factors (oxygen, NO_3^- , and C), which in turn are controlled by several physical and biological factors. Denitrification N loss can reach 10% of the fertilizer N input—more on grassland and when manure is also applied.^[11] Chemical denitrification is normally insignificant and is mainly related to the stability of NO_2^- and acid conditions.^[12] It is more difficult to reduce N_2O and NO from soils than NH_3 losses. A general principle is to minimize N surpluses in the soil profile via careful fertilizer adjustment, corresponding to the actual crop demands.

Leaching

Applied NO_3^- or NO_3^- , formed through nitrification from mineralized NH_4^+ or from NH_4^+ from animal manure, can leach out of the rooting zone. It is well possible that this leached NO_3^- can be denitrified at other places and returned into the atmosphere. The amount and intensity of rainfall, quantity and frequency of irrigation, evaporation rate, temperature, soil texture and structure, type of land use, cropping and tillage practices, and the amount and form of fertilizer N are all parameters influencing the amount of NO_3^- leaching to the underground water. NO_3^- leaching should be kept under control, as it may influence the NO_3^- content in drinking water influencing human health and in surface water causing eutrophication. NO_3^- losses can be minimized by reducing the mineral N content in the soil profile during the winter period by careful fertilizer adjustment, growing of cover crops, or riparian buffer areas.

Nitrogen Index

Jorge A. Delgado

Soil Plant Nutrient Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Fort Collins, Colorado, U.S.A.

Abstract

Nitrogen (N) is the key for humanity in the 21st century to help us achieve food security. Adding N inputs to agricultural systems contributes to higher crop yields; however, when inputs are higher than crop needs, the excess N can be lost to the environment via different pathways and contribute to negative impacts on air and water quality. There is a need to continue improving N management practices to increase N use efficiencies and reduce losses of N to the environment. The N index is a quick tool and approach that can provide needed information to nutrient managers to quickly assess the effects of management practices on the potential risk of N losses via different pathways. By quickly identifying these risky management landscape scenarios, better management practices for the site could be implemented. The N index can provide important agronomical and environmental information to nutrient managers to help them make improved management decisions.

NITROGEN (N) IS KEY TO SOLVE THE CHALLENGE OF ACHIEVING GLOBAL FOOD SECURITY

The global human population is projected to increase by 2 billion people by 2050 to a total population of approximately 9.5 billion people.^[1] At the same time, improved economies around the globe are contributing to healthier diets with higher demand for protein from livestock and dairy products.^[2] These factors are projected to contribute to greater global demand for calories over the next few decades. We must increase crop production to meet this increased demand for calories and protein and feed the 9.5 billion people who will be living on the earth by 2050.^[2] Humans will have to produce 70% more food during the next few decades.^[3]

Both crops and animals respond to N inputs, and N will be key to feeding humanity during the next few decades since it will contribute to increases in food production per area as well as to improved, higher protein diets. N inputs will be key for increasing grain, livestock, and dairy product production. Conservation of natural resources will be key for sustaining higher agricultural production. In particular, managing the N cycle to reduce losses of reactive N to the environment will be important. In other words, good management practices to manage the N cycle will be essential.

Among other great challenges are irrigation systems that are threatened by overpumping of groundwater resources and reduction of snowpack. Sustainability of irrigation systems is key because, on average, these systems are more productive per average unit of land than nonirrigated systems. To increase the production of these

irrigated systems to 200% or 300% higher than that of nonirrigated systems, N inputs are essential. However, these systems need to be managed with improved irrigation practices as well as best N management practices to reduce the potential for reactive N losses since these systems on average have a higher nitrate (NO₃) leaching potential, especially cropping systems with shallow root systems or when crops are grown over irrigated, coarse-textured soils. It has been reported that other pathways for NO₃ leaching include tile systems that accelerate the movement of NO₃ out of the root zone and typically into drainage ditches, contributing to the contamination of surface water with problems such as hypoxia in the Gulf of Mexico. On average, NO₃ leaching has been reported as the main or one of the main mechanisms for N losses.

Another challenge is the potential impacts of climate change on agricultural systems. It has been projected that climate change and extreme events will increase erosion rates. Similarly, droughts could also contribute to increased erosion rates. Soil erosion, besides removing important nutrients like N off-site, reduces productivity by an average of 4% for every 10 cm loss of soil, with higher loss in yields, as the soil continues to be eroded.^[4] As climate change contributes to higher erosion rates, it is expected that these higher erosion rates will contribute to increased off-site N impacts since the transport of N off-site will increase. Fortunately, conservation practices will help reduce these higher erosion rates expected to result from climate change and extreme events and will contribute to climate change adaptation.

There are other general challenges such as desertification, deforestation, and conversion of productive lands to urban centers. If we maximize agricultural production,

we need to increase productivity ahead of all of these challenges that humanity is facing, and N inputs will be key for increasing grain and forage production to meet the higher demand for meat and dairy products. N will be essential for meeting the demand for agricultural and animal products for feed, biofuels, meat, and dairy products. Worldwide food security will be connected to good stewardship and good N management practices that increase productivity while minimizing environmental impacts of N.

ENVIRONMENTAL CHALLENGES AND N MANAGEMENT

N has contributed to food security across a large number of regions; however, in addition to the significant positive impacts of N use that have been reported, it has also been reported that inputs of organic and inorganic N fertilizers have contributed to increased losses of N. These increased flows of N out of agricultural systems are contributing to an increase in losses of reactive N via surface runoff, NO_3 leaching, nitrous oxide (N_2O) emissions, ammonia (NH_3) volatilization, and other pathways. These losses of N contribute to a phenomenon known as the N cascade, where there are multiple effects as the reactive N is cycled through the environment.^[5]

It has been reported that surface N losses, as well as NO_3 leaching losses via tile systems, are pathways for N losses that contribute to negative impacts on surface water (e.g., hypoxia, higher cost at drinking water plants to remove NO_3 from water). NO_3 leaching losses have contributed to negative impacts on groundwater quality by increasing background NO_3 -N levels. The U.S. Environmental Protection Agency has reported that drinking water with NO_3 -N concentrations above 10 ppm is unsafe for human consumption, requiring that the NO_3 is removed from the water before it can be used by urban centers and/or rural communities connected to potable water from drinking water plants.^[6] The cost of removing the NO_3 from water in the United States has been estimated at \$4.8 billion per year, and of this cost, an estimated \$1.7 billion per year is from the NO_3 -N coming from agricultural sources.^[7]

Atmospheric losses of reactive N can contribute to negative impacts on air quality. Emissions of NH_3 have been reported to increase the concentrations of particulate matter 2.5, which can potentially impact air quality. It can also contribute to the transport of N to natural areas and impact natural agroecosystems by contributing to shifts in plant ecosystems.^[8] Atmospheric emissions of N_2O are also impacting air quality. The Intergovernmental Panel on Climate Change has reported that atmospheric emissions of N_2O can contribute to global warming and climate change, and emissions of N_2O from agricultural systems are an important source of greenhouse gas emissions. In the United States, the major contributor to emissions of

greenhouse gases from agricultural systems is N_2O emission from soils.^[9] In the United States, N_2O is contributing to about 80% of the greenhouse gas emissions from agriculture in carbon dioxide equivalents. About 20% of these carbon dioxide equivalent emissions are due to the indirect losses of reactive N to the environment (e.g., NH_3 volatilization and NO_3 leaching).

Management can potentially be used to reduce N losses to the environment. We could use, for example, nitrification inhibitors and controlled-release fertilizers to slow down the conversion of NH_4 to NO_3 -N to reduce the potential for NO_3 leaching.^[10,11] These practices also reduce the emission of N_2O .^[10,11] We could use precision agriculture to improve the spatial and temporal management of N by applying the right source of N and the right rate of N, at the right place and at the right time, to increase its use efficiency and reduce the losses to the environment. Precision conservation goes a step further and contributes to reduced losses of N to the environment at the field level and to reduced transport of N through the landscape, by implementing practices at the field and farm level to reduce off-site transport. There is potential to increase N use efficiency and reduce transport of N by applying the right fertilizer, with the right method of fertilizer application, with the right source of fertilizer, applied with the right conservation practice, with the conservation practice applied at the right scale and at the right place, and with the fertilizer and conservation practice applied at the right time.

PREVIOUS N INDEX WORK

There is potential to use quick assessments of management practices to assess the potential risk of N losses to the environment.^[12,13] There is also potential to use a tiered approach to manage N.^[12] The N index is a tier-one tool that is simple to use but robust enough to quickly assess the effects of a given set of management practices on the potential risk of N loss (ranked as low, medium, or high risk) using information on soil properties and soil hydrology, crop N uptake, inorganic and organic N inputs, and weather. Tier-two and tier-three tools are more complex tools and approaches that require more time for calibration to implement N management practices.

Several authors have reported on several different indices and on the advantages and disadvantages of these indices.^[12,14] The leaching index was the initial work that accounted for soil and climate and how it potentially influenced NO_3 -N leaching.^[15] However, the initial leaching index was more like a percolation water index since it was not tied to N management or N inputs.^[15,16] Among other indices reported in the literature^[12,17] are the movement risk index, the NO_3 -N available for leaching index, the residual NO_3 -N index, NO_3 leaching hazard index, the N use efficiency index, annual leaching risk potential index, and the aquifer risk index.

Each one of these indices has some advantages and disadvantages. For example, some of the indices do not estimate the actual $\text{NO}_3\text{-N}$ leaching. Additionally, some of the indices are not tied to N management practices and do not account for estimated crop N uptake or estimated N dynamics and N sources. Some of the indices do not estimate the impact of crop rotations or rooting depths. Some of the indices do not account for hydrological properties or irrigation events or water budgets. Some of the indices do not account for potential NO_3 leaching during the off-season or do not consider off-site factors. Shaffer and Delgado proposed an N index that integrates these factors and that can be used as a tier-one tool to quickly conduct a robust estimate of the potential risk of N losses to the environment.^[12]

AN N INDEX FOR RISK ASSESSMENT AND IMPROVED N MANAGEMENT

The N index is a quick assessment tool that can be used to assess the potential risk of NO_3 leaching and of surface water and atmospheric impacts (Fig. 1). The tool assesses the effects of management practices and source of N fertilizer (e.g., use of organic manure inputs) by integrating information about management, weather, and site-specific soil properties to assess the potential risk for N losses via leaching, surface, and atmospheric pathways. The tool conducts an N mass balance to assess the losses via NH_3 volatilization, NO_3 leaching, denitrification, surface runoff, and N_2O emissions. The tool also estimates crop N uptake and residual soil NO_3 . Several peer-reviewed manuscripts have shown that the N index tool can be used to assess the effects of management practices on N losses for different cropping systems in the United States, Mexico, South America (Bolivia and Ecuador), Africa (Malawi), and a Mediterranean region of Spain.^[18]

Shaffer and Delgado reported on a tiered approach for the assessment of N management practices, describing tiers-two and three as having a data-intensive approach, requiring more time to set up the needed information, and being used in coordination with field studies.^[12] In contrast, a tier-one tool is easy to use, is faster, and requires minimal information. The tier-zero tool is even easier to use than a tier-one tool, with just a few screens and minimal information required, and which provides a robust analysis of N management practices and a qualitative and quantitative assessment of the potential risk of N losses (Fig. 1).

The N index is easy to use, and it takes into consideration the effects of management of fertilizer, manure, crops, irrigation, soils, climate, and off-site factors. The N index also integrates the use of best management practices being applied at the site when assessing the potential risk of N losses to the environment. The N index accounts for N management practices and estimates the crop N uptake, N dynamics, and N sources. It also accounts for crop rotations

Fig. 1 Version 4.5 of the Nitrogen Index, a national and international tool.

and rooting depth. It integrates soil hydrology properties and water inputs as well as estimated water leaching. It accounts for precipitation during the growing season and nongrowing season and estimates $\text{NO}_3\text{-N}$ leaching losses, direct and indirect N_2O emissions, surface N losses, denitrification, NH_3 volatilization, crop N uptake, and residual soil $\text{NO}_3\text{-N}$. The management can be entered for a given crop at a site-specific location, and the tool will estimate the potential risk for N losses as well as the cropping system N use efficiency. The tool integrates soil management principles, soil chemical and physical principles, hydrological principles, and ecological engineering principles to assess the potential risk of N losses and help the user make management decisions (Fig. 2).

The N index can be joined to other nutrient indices and be used to help users assess practices with multiple indexes in one screen. The Kentucky N and phosphorous (P) index is one such example (Fig. 3).^[19] The N index can be used as an important tool for conservation management by integrating this approach into nutrient management plans.^[20] The tool is being used in California and is the official tool in the Natural Resources Conservation Service (NRCS) 590 nutrient management standards for Kentucky and Wisconsin. It has been transferred to NRCS—South

Fig. 2 Recommendation Screen of the Nitrogen index (version 4.5), a national and international tool.

Fig. 3 Assessment of Risk Screen of the Kentucky Nitrogen and Phosphorus Index.

Dakota and to several international institutions such as Instituto Nacional de Investigaciones Forestales, Agrícolas y Pecuarias (INIFAP; in Mexico), Colegio de Estudios de Posgrado (COLPOS; in Mexico), Fundación para la Promoción e Investigación de Productos Andinos (PROINPA; in Bolivia), Instituto Nacional de Investigaciones Agropecuarias (INIAP; in Ecuador), University of Brasilia (in Brazil), and the Ministry of Agriculture and Food Security (in Malawi). The tool can be used in English, Spanish, and Portuguese. The tool can be used in metric or English units.

AN N INDEX FOR FERTILIZER RECOMMENDATIONS

Users of the N index can quickly enter the information on soil, weather, management, hydrology, weather, and expected yields. The user could select the source of inorganic N that is being applied (e.g., urea) and method (e.g., incorporated) from drop-down menus and enter the amount applied. Similarly, the user can enter the type of manure added to the field (e.g., liquid or dry), the method (e.g., incorporated), and the amount. Once the user has entered all the information into the tool, which just takes a few minutes, it is possible to proceed to the output screen. The user could select the recommendations screen to try to assess whether, when accounting for all the N sources, there is potential to apply less N while providing enough N for the crop uptake demand. The user could then go back to the N fertilizer and manure screens and change the N inputs. The user could then go back to the outputs screen to determine whether the changes in management provide enough N to the crop while reducing the N losses to the environment.

A QUICK N INDEX TOOL FOR 590 NUTRIENT MANAGEMENT PLANS

The N index has been adopted by NRCS as a quick assessment tool. The tool has been transferred to NRCS—California, NRCS—South Dakota, NRCS—Kentucky, and NRCS—Wisconsin. The tool has been adopted as the official tool for the 590 nutrient management plans in Kentucky^[19] and Wisconsin. The Kentucky N index also includes the assessment of potential risk of P losses to the environment. The tool can be used to help users assess the risk of reactive N losses to the environment and to make management decisions that can reduce the losses of reactive N. The N index tool has the potential to be used for other 590 nutrient management plans and for improving N management.

CONCLUSION

N is key for the humanity in the 21st century. N is part of our bodies, and protein inputs are important in the human diet.

However, N is also needed to maximize calorie production in the field because crops respond significantly to N inputs. To fulfill the daily caloric needs of the increasing human population during the 21st century, N will be key, especially in these challenging times when we confront big challenges such as a changing climate, depletion of water resources across different key agroecological systems, conversion of productive land to urban centers, and other great challenges. So adding N inputs to agricultural systems is the right approach for food security. However, we also need to conserve water, soil quality, and air quality, and N is also connected to environmental challenges.

There is a need to improve the management of N inputs to agricultural systems because they increase the potential for losses of reactive N to the environment, resulting in negative impacts on water and air resources. There is a need to reduce NO₃ leaching, emissions of N₂O from agricultural systems, N losses to surface water, and other losses of reactive N. There is a need to increase N use efficiencies across agroecosystems. The N index is a quick approach that can provide needed information to nutrient managers to quickly assess the effects of management practices on the potential risk of N losses via different pathways so nutrient managers could identify situations where risky combinations of management practices and landscape scenarios increase the potential for reactive losses of N (e.g., NO₃ leaching and N₂O emissions). By quickly identifying these risky management landscape scenarios, better management practices for that site could be implemented. The N index can provide important agronomical and environmental information to nutrient managers to help them make improved decisions. It can use an N balance to develop management recommendations. The U.S. Department of Agriculture—NCRS has started to apply the N index in state 590 nutrient management plans. The tool can be used in different languages and is being used in different countries and continents. The N index can be run in English or metric units. Similar to the P index that can assess the potential risk of P losses to the environment, the N index can be used to quickly assess the risk of N losses to the environment to improve N management, reduce losses of reactive N, increase N use efficiencies, and improve economic returns for farmers.

Abstract

Nitrogen-15 (^{15}N) stable isotope has been and is a very useful tool to know the complexity of N cycling in soil. An ^{15}N isotope can be used to study N fertilizer efficiency, mineralization, nitrification, immobilization, leaching, etc. It helps to reduce the negative environmental impact of N fertilizer. The main limitation of ^{15}N is the high cost of the equipment for analysis and enriched fertilizer.

INTRODUCTION

Research in the past has supplied abundant information regarding many factors and processes that influence nitrogen (N) availability in soils. Many of these advances have resulted from the studies performed with the enriched nitrogen-15 (^{15}N) stable isotope. This isotope has been indispensable in knowing the rate of N in soil-plant systems. Two types of studies are performed with ^{15}N , namely studies of natural abundance levels and studies of enriched levels (^{15}N -labeled). In both these types of studies, the isotope content is measured with a mass spectrometer. The main uses of ^{15}N have been to determine the efficiency in the use of N fertilizer, the biological fixation of atmospheric nitrogen gas (N_2) by legumes, N balance, N transformation in soils, N availability from organic materials, the estimation of N rhizodeposition and root biomass, and studies on animal nutrition. The main limitation for the use of ^{15}N is the high cost of the equipment for analysis as well as the enriched fertilizers.

THE ^{15}N ISOTOPE

The most common N isotope has an atomic weight of 14. There is a heavier isotope, ^{15}N , which has one neutron more than the most abundant form (^{14}N). The ^{15}N concentration in air is very stable, reaching 0.3663% ($\pm 0.0004\%$) of the N in the atmosphere, with the rest as (99.6%) ^{14}N . This concentration is known as natural abundance. All fertilizers

with ^{15}N concentrations found outside the range of natural abundance are referred to as enriched.

The ^{15}N enrichment of any sample is expressed as the percentage of ^{15}N atoms in excess and is determined according to the following equation:

$$\% \text{ atom } ^{15}\text{N excess} = \% \text{ atom } ^{15}\text{N}_{\text{sample}} - \% \text{ atom } ^{15}\text{N}_{\text{air}} \quad (1)$$

where the % of ^{15}N atoms in the air is the natural abundance.

The most common method used to apply ^{15}N is through the use of enriched N fertilizer, presented in uric, nitric, or ammonial form or a combination of these, with enrichments that range between 2.5% and 99% ^{15}N atoms, being able to distinguish between fertilizers with only a fraction of enriched N or where all the N atoms present are ^{15}N .

N FERTILIZER RATE

The ^{15}N technology has allowed the N processes in soil to be examined, making it possible to identify the labeled forms of N and how these forms enter the system, transform, and even leave the system studied with adequate accuracy and precision.^[1] Nevertheless, there are limitations due to the internal biological recycling, which occurs in the soil, making the interpretation of ^{15}N data a meticulous work.^[2]

This technique is normally applied in mass balance studies in which the following premises are assumed:^[3]

1. The labeled and unlabeled materials have the same chemical behavior.
2. The pool that constitutes the N source is considered uniformly labeled by the isotope.
3. The addition of the isotope does not stimulate the transformation rate.

Once these premises are satisfied, by labeling the soil with $^{15}\text{NH}_4^+$ or $^{15}\text{NO}_3^-$, it is possible to determine the following:^[2,3]

1. mineralization rates, through the decrease in ^{15}N enrichment of $^{15}\text{NH}_4^+$;
2. nitrification, by studying the decrease in ^{15}N enrichment of NO_3^- ;
3. consumption/removal or immobilization of NH_4^+ or NO_3^- , through the disappearance of labeled ^{15}N ;
4. leaching and volatilization; and
5. the processes that exploit the ^{15}N and ^{14}N in all of the available pools, proportionally to its relative amounts.

To estimate the efficiency of N fertilizer using ^{15}N , a labeled fertilizer is added to the soil, and the amount of N fertilizer absorbed by the plant is determined. Different practices can be studied in this way, such as the type of fertilizer, time of application, location, and rate. In studies with ^{15}N -enriched fertilizers, the percentage that the plant nitrogen derived from the fertilizer (Ndff) is calculated on the following basis:

$$\text{Ndff}(\%) = \frac{\% \text{ } ^{15}\text{N excess}_{\text{sample}}}{\% \text{ } ^{15}\text{N excess}_{\text{fertilizer}}} \times 100 \quad (2)$$

The fertilizer nitrogen utilization efficiency (FNUE) is calculated according to the following equation:

$$\text{FNUE}(\%) = \frac{\text{N uptake} \times \text{Ndff}}{\text{Rate of N applied}} \times 100 \quad (3)$$

DETERMINATION OF BIOLOGICAL N_2 FIXATION

The methods that use ^{15}N have been highly used to understand the biochemistry of N_2 fixation by microorganisms. The study of the factors that influence the symbiotic fixation of N_2 also includes the evaluation of the fixation capacity of each microorganism, in addition to the quantification of the translocation of fixed N through the system (soil or plant).

The ^{15}N abundance in the environment is determined through the analysis of a reference plant (non-N-fixing plant) that is completely dependent on the N present in the soil for growth. The N_2 fixation can be determined by measuring the changes produced in the enrichment of ^{15}N in the fixing plant as a consequence of the assimilation of atmospheric N_2 . Various methods have been developed to determine N_2 fixation using ^{15}N . The most highly used methods are discussed in the following subsections.

^{15}N Dilution Method

The ^{15}N dilution method allows each of the different N sources of the plant to be evaluated. Before sowing, the application of a small amount of ^{15}N -enriched fertilizer is required, ranging from 1 kg/ha to 10 kg/ha with 1–10% N atoms in excess, with the objective of reducing any possible interference with the fixing capacity of the legume. The proportion of N of the plant from symbiotic fixation and from the soil can be calculated if the isotopic abundance between these two sources is different. This difference is obtained by comparing the ^{15}N enrichment of the nodulated legume with that of the plant used as a reference (non-fixing). The following equation is used to determine the plant nitrogen derived from the air (Ndfa):

$$\text{Ndfa}(\%) = \frac{1 - \% \text{ atom } ^{15}\text{N excess}_{\text{legume}}}{\% \text{ atom } ^{15}\text{N excess}_{\text{reference}}} \times 100 \quad (4)$$

The ^{15}N enrichment of the N derived from the soil present in the legume is determined from the ^{15}N enrichment of the reference plant, which should have grown in the same soil and at the same time as the legume. The use of this method implies the assumption of the following premises:

1. The $^{14}\text{N}/^{15}\text{N}$ ratio in the reference plant is the same as N ratio of the soil.
2. Both the legume and the reference plant explore the same volume of soil with an identical $^{14}\text{N}/^{15}\text{N}$ ratio.
3. Both plants should absorb the same relative amount of ^{15}N .
4. The dynamic of N absorption is same for both plants, as this is the most frequent cause of error when the fixed N_2 is determined using this method.

^{15}N Natural Abundance Method

This method is a variation of the isotopic dilution technique, based on the small differences in ^{15}N natural abundance between atmospheric N_2 and soil N. These differences are expressed as delta (δ) ^{15}N , which indicates the amount of ^{15}N with respect to the ^{14}N that exists in a sample, expressed in parts per thousand (‰). Elevated δ values indicate large amounts of ^{15}N . By definition, the standard considered (0.3663) has $\delta = 0\text{‰}$. Positive δ values indicate that the sample contains more ^{15}N than the standard, whereas the opposite is true for negative δ values. The calculation used is given as follows:

$$\delta^{15}\text{N}(\text{‰}) = \frac{\% \text{ atom } ^{15}\text{N}_{\text{sample}} - \% \text{ atom } ^{15}\text{N}_{\text{standard}}}{\% \text{ atom } ^{15}\text{N}_{\text{standard}}} \times 1000 \quad (5)$$

Soils are more enriched in ^{15}N (with a $\delta^{15}\text{N}$ of up to 16‰) than the atmosphere ($\delta^{15}\text{N} = 0\text{‰}$). This enrichment is due to the processes of isotopic discrimination and

denitrification, as well as other N transformations in the soil. The percentage of atmospheric N₂ fixed by the legume or Ndfa is calculated using the following equation:^[4]

$$\text{Ndfa}(\%) = \frac{\delta^{15}\text{N}_{\text{reference}} - \delta^{15}\text{N}_{\text{legume}}}{\delta^{15}\text{N}_{\text{reference}} - \text{B}} \times 100 \quad (6)$$

with B factor as the $\delta^{15}\text{N}$ of the legume that grows with atmospheric N₂ as it is the only source of N. Theoretically, the B value is 0‰ if it is assumed that no isotopic fractionation occurs. Considering that the soil N is generally more abundant in ^{15}N than in the atmospheric N₂, the reference plant is expected to have higher δ values than the legume, which obtains N from both the soil and the air. The $\delta^{15}\text{N}$ values in the plants used as reference present a high variability, where the $\delta^{15}\text{N}$ values can fluctuate by several units in plants separated by several centimeters.^[5,6]

The most significant advantages of this methodology with respect to the dilution technique can be summarized as follows:

1. It does not require the addition of ^{15}N .
2. The soil $\delta^{15}\text{N}$ values are relatively constant with depth and time.
3. The reference plant selection is not as important, taking precautions with the proximity of the fixing plants.

The following limitations of this methodology are worth mentioning:^[7]

1. It requires great meticulousness and precision in the analytic processes.
2. The B factor must be determined for each legume.
3. The technique is inappropriate if the $\delta^{15}\text{N}$ values of the soil are close to those of the air. For this reason, it is recommended that the soil $\delta^{15}\text{N}$ be greater than 5‰.
4. Small variations in the $\delta^{15}\text{N}$ values correspond to substantial variations in the estimation of N₂ fixation.

ESTIMATION OF N RHIZODEPOSITION

N rhizodeposition (N derived from the root exudates as well as the decomposition of fine roots) has been estimated with different methodologies. To determine the proportion of N present in the soil derived from rhizodeposition (NdfR), the plants must be labeled with ^{15}N . Subsequently, the ^{15}N flow is studied from the aerial part of the plant to the roots and then to the soil.^[8]

Because the N rhizodepositions are susceptible to being extracted again by plants and microorganisms, absorbed in the soil particles or lost from the system, the data always offer the resulting net rhizodeposition and related processes.^[9] The high ^{15}N enrichment of the fertilizer used in this technique (greater than 98%) allows for better

detection of the isotope even in small soil fractions. Five methods have been tested for effectiveness and practicability of plant ^{15}N labeling to study the N rhizodeposition as follows:^[10]

1. Root feeding:^[11] Roots of hydroponic plants are immersed in nutrient solution containing ^{15}N for 48 hours.
2. Vacuum infiltration:^[10] Roots of hydroponic plants are enclosed in a wet tissue paper/polythene sheet to prevent desiccation and ^{15}N contamination of the roots. Plants are turned upside down, and the leaves are immersed in labeling solution. After transfer to a desiccator, the plants are evacuated to 170 mbar for 5 minutes. Thereafter, the plants are left under the atmospheric pressure in the climate chamber for a further 48 hours.
3. Surface abrasion:^[10] The surface of the representative leaves of intact plants is abraded with sandpaper. Tissue paper is soaked with a labeling solution and is attached and fixed to the treated leaves for 48 hours.
4. Stem infiltration:^[12] A cotton wick is inserted into a hole in the stem of each plant. The wick is covered with siphon plastic tubing and connected to a reservoir containing the labeling solution. The height of wick insertion in relation to the reservoir is selected to avoid the dripping of the labeling solution into the rooting substrate (nutrient solution or soil). The reservoir is refilled with the labeling solution when necessary over the following 48 hours.
5. Leaf tip feeding:^[8] Leaf tips are cutoff, and the de-tipped grass blades are bent into glass reaction vials where they are immersed in labeling solution from 48 hours to 7 days. The leaves are fixed into this position with adhesive tape.

The NdfR is determined using the following equation:^[8]

$$\text{NdfR}(\%) = \frac{\% \text{ atom } ^{15}\text{N}_{\text{excess soil}}}{\% \text{ atom } ^{15}\text{N}_{\text{excess roots}}} \times 100 \quad (7)$$

The amount of rhizodeposited N (kg/ha) is estimated as follows:

$$\text{NdfR}(\text{kg/ha}) = N_s \times \frac{\text{NdfR}(\%)}{100} \quad (8)$$

where N_s = N content in the soil or soil fraction (kg/ha). The accuracy of estimating N rhizodeposits increases with increased enrichment of the plant roots and with a decreasing soil N content.^[11] However, it is crucial to include unlabeled control treatments, where the isotopic composition of plant and soil pools is measured and used as a background for calculating the atom % ^{15}N in excess values, instead of using the natural ^{15}N abundance of atmospheric N₂ (0.3663 at % ^{15}N).

CONCLUSION

^{15}N is a crucial tool to research N dynamic in soil–plant system. The results of studies with ^{15}N have reduced environmental impact of N fertilization and have improved the knowledge about the important role of legume crops in the sustainable agriculture.

Nitrous Oxide Emissions: Agricultural Soils

John R. Freney

Plant Industry, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australian Capital Territory, Australia

Abstract

Nitrous oxide emissions from agricultural soils are generally greater and more variable than those from uncultivated land. All soils are deficient in nitrogen (N) for the growth of plants, but the deficiency can be overcome by adding fertilizer N. The low efficiency of fertilizer N in agricultural systems is primarily caused by the large losses of mineral N from those systems by gaseous loss: nitrous oxide emission is directly linked to the loss processes.

INTRODUCTION

Nitrous oxide is a gas that is produced naturally by many different microorganisms in soils and waters, and as a result of human activity associated with agriculture, biomass burning, stationary combustion, automobiles, and the production of nitric and adipic acids for industrial purposes. According to the Intergovernmental Panel on Climate Change (IPCC),^[1] ~23.1 million metric tons (Mt) of nitrous oxide is emitted each year, 14.1 Mt as a result of natural processes (~4.7 Mt from the oceans, ~6.3 Mt from tropical soils, and ~3.1 Mt from temperate soils) and ~9Mt as a result of human activities (5.5 Mt from agricultural soils, 0.6 Mt from cattle and feedlots, 0.8Mt from biomass burning, and 2.1 Mt from mobile sources and industry). While there is considerable uncertainty associated with each of these estimates, it is apparent that most nitrous oxide is derived from soils.

Because of the intimate connection between the earth and the atmosphere, much of the nitrous oxide produced enters the atmosphere and affects its chemical and physical properties. Nitrous oxide contributes to the destruction of the stratospheric ozone layer that protects the earth from harmful ultraviolet radiation and is one of the more potent greenhouse gases that trap part of the thermal radiation from the earth's surface. The atmospheric concentration of nitrous oxide is ~313 parts per billion. It is increasing at the rate of ~0.7 parts per billion each year, and its lifetime is ~166 years.^[2] It seems that the increased atmospheric concentration results from the increased use of synthetic fertilizer nitrogen (N), biologically fixed N, animal manure, crop residues, and human sewage sludge in agriculture to produce food and fiber for the rapidly increasing world population.^[3]

NITROUS OXIDE EMISSION FROM AGRICULTURE

All soils are deficient in N for the growth of plants, but the deficiency can be overcome by adding fertilizer N. When

the fertilizer (e.g., urea or ammonia-based compounds) is applied to soil, it is transformed by microorganisms as follows

When the soil is aerobic (i.e., when oxygen is present), ammonium is oxidized to nitrite and nitrate (Steps 2 and 3). This process is called nitrification. After the addition of irrigation water or rain, the soil may become anaerobic (devoid of oxygen). The nitrate is then reduced by soil organisms to nitrite and the gases, namely nitric oxide, nitrous oxide, and dinitrogen (Steps 4–7) in a process termed denitrification.^[4]

When atmospheric scientists first expressed concern that nitrous oxide emission into the atmosphere, as a result of fertilizer use, would lead to destruction of the ozone layer, it was thought that nitrous oxide was produced mainly from the microbiological reduction of nitrate in poorly aerated soils. However, research in the latter part of the 1970s showed that significant nitrous oxide was emitted from aerobic soils during the nitrification of ammonium, and subsequent work has shown that nitrification is a major source of nitrous oxide.^[4]

Nitrous Oxide from Denitrification

Certain microorganisms in the absence of oxygen have the capacity to reduce nitrate (or other N oxides). Most denitrifying bacteria are heterotrophs—i.e., they require a source of organic matter for energy—but denitrifying organisms that obtain their energy from light or inorganic compounds also occur in soils. The capacity to denitrify has been reported in more than 20 genera of bacteria, and almost all are aerobic organisms that can

only grow anaerobically in the presence of N oxides. The dominant denitrifying organisms in soil are *Pseudomonas* and *Alcaligenes*. In addition to the free-living denitrifiers, rhizobia living symbiotically in root nodules of legumes are able to denitrify nitrate and produce nitrous oxide.^[4]

The general requirements for biological denitrification include the presence of microorganisms with denitrifying capacity, nitrate (or other N oxides) and available organic matter, the absence of oxygen, and a suitable pH and temperature environment. In aerobic soils, denitrification can occur in anaerobic microsites in soil aggregates or in areas of high carbon content, where active microbial activity rapidly consumes all of the available oxygen.^[4]

Nitrous Oxide from Nitrification

The process of nitrification is normally defined as the biological oxidation of ammonium to nitrate with nitrite as an intermediate.^[4] The first step in the reaction, the oxidation of ammonium to nitrite, is carried out mainly by the microorganism *Nitrosomonas*. The second step, the oxidation of nitrite to nitrate, is carried out by *Nitrobacter*. It has been shown in a number of publications that *Nitrosomonas europaea* produces nitrous oxide during the oxidation of ammonium.^[4]

The possibility that significant nitrous oxide can be produced in soils by nitrifying organisms was indicated by studies that showed that soils incubated under aerobic conditions with ammonium produced more nitrous oxide than soils amended with nitrate.^[4] In addition, treatment of aerobic soils with nitrapyrin, which inhibits the nitrification of ammonium but has little effect on denitrification, markedly reduced the emission of nitrous oxide.^[4] The production of nitrous oxide by nitrification in soils is increased by increasing temperature, pH, water content, available carbon, and the addition of ammonium-based fertilizers, plant residues, and animal manure.

Flooded Soils

In the past few years, increased attention has been given to nitrous oxide emission from paddy soils. The concern is that the introduction of management practices to reduce methane emissions from flooded soils may result in increased emissions of nitrous oxide.

Flooded soils are characterized by an oxygenated water column overlying an oxidized layer at the soil–water interface, an aerobic zone around each root, and anaerobic conditions in the remainder of the soil. This differentiation of the flooded soil into oxidized and reduced zones has a marked effect on the transformation of N.^[5] The resulting reactions are as follows:

1. Ammonium in the reduced zone diffuses to the oxidized zone;
2. Ammonium is oxidized to nitrate by nitrifying organisms;
3. The nitrate formed diffuses to the anaerobic zone;
4. Denitrification occurs with the production of nitrous oxide and dinitrogen; and
5. The gaseous products diffuse through the soil and water layers to the atmosphere.^[6]

It is apparent that the rate of diffusion of ammonium to an oxidized layer and the rate of nitrification in the oxidized layer are factors controlling the production of nitrous oxide in flooded soils. The rate of diffusion of nitrous oxide through the soil and water layers will control its rate of emission to the atmosphere, or its further reduction to dinitrogen.^[5]

A number of mechanisms have been identified for the transfer of nitrous oxide from the soil to the atmosphere.^[3] Nitrous oxide may diffuse from the zone of production through the saturated soil and water layer to the atmosphere. It may also enter the roots of the rice plant and move by diffusion through the plant to the atmosphere in the same way as methane. Bhadrachalam et al.^[6] studied the importance of the two pathways in intermittently flooded rice in the field in India and found that N gas fluxes were ~30% greater when transfer through the plants was included.

In the tropics, rice is usually transplanted and fertilized sometime after flooding. Because of the anaerobic conditions that develop before fertilization and the slow rate of diffusion of nitrous oxide in flooded soils, most of the nitrous oxide is reduced to dinitrogen and very little escapes to the atmosphere. Nitrous oxide emission from intermittently flooded rice was relatively large compared with that from permanently flooded rice, reflecting the different oxidation states of intermittently and continuously flooded soils.^[6] Studies of nitrous oxide emission from rice fields from the time the soils were drained for harvest, through flooding the soil in preparation for planting the next crop, showed that nitrous oxide was emitted continuously while the soil was not flooded. Overall, the rate of emission of nitrous oxide from flooded soils was less than that from upland soils after the application of N fertilizer.^[3]

Biomass Burning

During combustion, the N in the fuel can be converted into gaseous forms such as ammonia, nitric oxide, nitrous oxide, dinitrogen, and hydrogen cyanide. It is estimated that biomass burning contributes between 0.3 and 1.6 Mt nitrous oxide per year globally to the atmosphere.^[3] Most of the biomass burning (~90%) takes place in the tropics as a result of forest clearing, savanna

and sugarcane fires, and burning of agricultural wastes and firewood.^[7]

Biomass burning is not only an instantaneous source of nitrous oxide, but it also results in a longer term enhancement of the production of this gas. Measurements of nitrous oxide emissions from soils, before and after burning, showed that significantly more nitrous oxide was exhaled after the burn through alteration of the chemical, biological, and physical processes in soil.^[7]

Fertilizer Consumption and Nitrous Oxide Production

Nitrous oxide emissions from agricultural soils are generally greater and more variable than those from uncultivated land. The application of fertilizer N, animal manure, and sewage sludge usually results in enhanced emissions of nitrous oxide.^[7] Generally, there is a large emission of nitrous oxide immediately after the application of fertilizer. After about 6 weeks, the emission rate falls and fluctuates around a low value. Mosier^[8] concluded that interactions between the physical, chemical, and biological variables are complex, that nitrous oxide fluxes are variable in time and space, and that soil management, cropping systems, and variable rainfall appear to have a greater effect on nitrous oxide emission than the type of N fertilizer. Consequently, Mosier et al.^[9] recommend the use of one factor only for calculating the emission of nitrous oxide from different fertilizer types

$$\text{N}_2\text{O emitted} = 1.25\% \text{ of N applied (kg N/ha)} \quad (2)$$

This equation is based on data from long-term experiments with a variety of mineral and organic fertilizers and encompasses 90% of the direct contributions of N fertilizers to nitrous oxide emissions.

Mosier et al.^[3] developed a methodology to estimate agricultural emissions of nitrous oxide, taking into account all of the N inputs into crop production. They included direct emissions from agricultural soils as a result of synthetic fertilizer addition, animal wastes, increased biological N fixation, cultivation of mineral and organic soils through enhanced organic matter mineralization, and mineralization of crop residues returned to the field. Indirect nitrous oxide emissions resulting from the deposition of ammonia and oxides of N, leaching of nitrate and the introduction of N into sewage systems were also included. They concluded that in 1989, 9.9 Mt of nitrous oxide was emitted into the atmosphere directly or indirectly, as a result of agriculture (Table 1).

MANAGEMENT PRACTICES TO DECREASE NITROUS OXIDE EMISSION

The low efficiency of fertilizer N in agricultural systems is primarily caused by the large losses of mineral N

Table 1 Calculated emission of nitrous oxide from agricultural activities.

Mt nitrous oxide per year	
Direct soil emissions	
Synthetic fertilizer	1.4 (0.28–2.5)
Animal waste	0.9 (0.19–1.7)
Biological nitrogen fixation	0.16 (0.03–0.3)
Crop residue	0.6 (0.11–1.1)
Cultivation of Histosols	0.16 (0.03–0.3)
Total	3.3 (0.6–5.9)
Animal production	
Waste management systems	3.3 (0.9–4.9)
Indirect emissions	
Atmospheric deposition	0.47 (0.09–0.9)
Nitrogen leaching and runoff	2.5 (0.2–12.1)
Human sewage	0.3 (0.06–4.1)
Total	3.3 (0.35–17.1)
Total	9.9 (1.9–27.9)

Source: Modified from Mosier, Kroeze, et al.^[3]

from those systems by gaseous loss: nitrous oxide emission is directly linked to the loss processes. It is axiomatic that any strategy that increases the efficiency of N fertilizer use will reduce the emissions of nitrous oxide, and this has been directly demonstrated for a number of strategies.^[3]

The IPCC^[1] reported that some combination of the following management practices, if adopted worldwide, would improve the efficiency of the use of synthetic fertilizer and manure N, and significantly reduce nitrous oxide emission into the atmosphere to

1. Match N supply with crop demand.
2. Tighten N flow cycles by returning animal wastes to the field and conserving residues instead of burning them.
3. Use controlled-release fertilizers, incorporate fertilizer to reduce volatilization, use urease and nitrification inhibitors, and match fertilizer type to precipitation.
4. Optimize tillage, irrigation, and drainage.

The potential decrease in nitrous oxide emissions from synthetic fertilizer, as a result of the mitigation techniques, could amount to 20%.^[1]

Nitrous Oxide Emissions: Paddy Soils

Jianfu Xue

Xin Zhao

Hailin Zhang

College of Agronomy and Biotechnology, China Agricultural University, Beijing, China

Abstract

Global warming is an increasing concern for scientists, policy makers, and public all over the world. Nitrous oxide (N_2O) is one of the most important anthropogenic greenhouse gases. Paddy fields are the primary sources of N_2O emissions due to mid-season and drying–wetting alternation during the growing season. Agricultural management practices (e.g., water management and fertilizers application) have great impacts on N_2O emissions because of the microenvironmental changes of paddy fields. A further understanding of the mechanisms of N_2O emissions and optimizing farming practices on paddy fields are of fundamental significance for the mitigation of climate change.

INTRODUCTION

Globally, climate change has become a significant issue and challenge to human well-being. Next to carbon dioxide and methane (CH_4), nitrous oxide (N_2O) is one of the principal anthropogenic greenhouse gases, which can result in an increased photolysis rate of stratospheric ozone due to the increase of N_2O concentration at an average rate of ~ 0.75 ppb yr^{-1} .^[1] The N_2O emissions from agriculture are the primary anthropogenic source, especially due to widespread use of synthetic and manure fertilizers. It has been reported that the amount of N_2O emissions from fertilizers, including the following subdomains with synthetic fertilizers, manure management, and manure applied to soils, are 2016.4, 680.8, 508.7, 116.4, and 40.4 Gg in Asia, the United States, Europe, Africa, and Oceania, respectively.^[2]

Paddy soils are not only the source of CH_4 emissions but also a significant source of N_2O emissions. For example, it is estimated that N_2O emission from paddy fields accounted for 22% of the total emission from croplands in China.^[3] It is critical to understand the mechanism of N_2O generation and the influencing factors of N_2O emissions from paddy soils in order to effectively mitigate climate change.

PATHWAYS OF N_2O EMISSION FROM PADDY SOILS

Soil N_2O as an intermediate product is primarily generated during the process of nitrification and denitrification. Generally, the main sources of soil N_2O are from nitrification under aerobic conditions and from denitrification under anoxic conditions.^[4] The oxidation process in nitrification

includes oxidizing ammonium (NH_4^+) to nitrite (NO_2^-) and oxidizing NO_2^- to nitrate (NO_3^-). In denitrification, oxidized inorganic forms of nitrogen (N) are sequentially reduced as follows: $\text{NO}_3^- \rightarrow \text{NO}_2^- \rightarrow \text{NO} \rightarrow \text{N}_2\text{O} \rightarrow \text{N}_2$ under anoxic/suboxic conditions. Paddy soils have a unique profile including oxidizing and reducing layers in the plow layer due to long-term flooding. Generally, N_2O is mainly generated through both nitrification in the oxidizing layer and denitrification in the reducing layer of paddy soils during rice (*Oryza sativa* L.) growing and non-growing seasons. However, less N_2O emission is released into the atmosphere through denitrification due to lower water content during rice non-growing season. Previous studies showed that 80% of N_2O emissions from paddy fields were released into the atmosphere through the rice plant under continuous flooding conditions.^[5] However, N_2O emissions from paddy soils mainly occurred during the drainage-drying periods. Compared with the flooding condition, 82.5% of N_2O emissions were released into the atmosphere through the soil surface under the drainage-drying period.^[6] In addition, additional research has been conducted concerning the influence of floodwater on the pathway of N_2O emission from rice plants.^[6] Cutting the rice stems below water surface can immediately decrease N_2O emission compared with cutting under flooded condition, while no variation is observed among uncut plants.^[6] However, there is almost an equal amount of N_2O emission after drainage flooding regardless of cutting the rice plants.

Water Regime

Water regime has a significant influence on N_2O emissions from paddy soils. Generally, less N_2O emission from paddy fields is observed under continuous flooding conditions

compared with non-flooding conditions during the rice-growing season. However, mid-season aeration and drying-wetting alternation are widely applied in rice production in order to save agricultural water and to increase rice yield, which can stimulate N_2O generation and emissions from paddy soils. The peak value of N_2O fluxes is observed during the mid-season aeration and drainage-drying period before the rice harvest. The N_2O emission during the drainage-drying phase accounts for 87–98% of the total N_2O emission in the whole rice-growing season.^[7] Li et al. also found that N_2O emissions during the mid-season aeration period and 5–8 days after reflooding can account for 70–94% of the total N_2O emission in the whole rice-growing season.^[8] But the N_2O emissions from paddy fields decrease gradually with the postponement of the mid-season aeration. Soil moisture status [e.g., water-holding capacity (WHC) and water-filled pore space (WFPS)] affects N_2O emission from paddy fields through changing soil aeration and redox potential. The largest N_2O emission in a paddy ecosystem is observed under 90–100% of WHC or 77–86% of WFPS.^[9] These peaks of N_2O emission in paddy soils are observed at different WFPS levels due to differences in soil types and cropping systems.^[9–11]

Fertilizer Application

Several studies have reported the effects of fertilizer application on N_2O emissions in paddy fields. The N_2O emission increases with increase in the application rate of N fertilizer regardless of the urea or NH_4^+ content of fertilizer during the rice-growing season,^[12] due to the supplement of NO_3^- and NH_4^+ substrate for the process of nitrification and denitrification. Differences in N_2O emissions could be observed with the application of different synthetic fertilizer types in paddy fields.^[13] The use of ammonium sulfate can lead to larger N_2O emissions than that of urea during the rice-growing season in paddy fields.^[13] The effects of diverse forms of N fertilizers on N_2O emissions from paddy fields indicate the following order, i.e., from the highest N_2O emissions to the lowest: anhydrous ammonia > NH_4^+ > calcium nitrate > ammonium nitrate > urea.^[14] In some cases, the adoption of controlled availability of fertilizer reduced N_2O emissions by 30% compared with urea during the whole rice-growing season in paddy fields,^[15] but the difference in N_2O emissions between the fertilizers was not always be observed.^[16] Such contradictory response may be due to the slow release and sustained release properties of controlled availability of fertilizer. The controlled release can hold higher NH_4^+ concentrations and promote nitrification during mid-season aeration, thereby accumulating NO_3^- , which benefits denitrification during reflooding and ultimately leads to the enhancement of N_2O emission. Fertilizer application methods also have a significant effect on N_2O emissions in paddy fields. Compared with surface broadcasting in paddy field, incorporating fertilizer into soil can reduce N_2O emissions. This trend

can be attributed to easier oxidation from NH_4^+ to NO_3^- in the surface solution and NO_3^- diffusion to deeper aerobic layer, which accelerates microbial denitrification for surface broadcasting practice.

However, there are more complex mechanisms by which organic fertilizers influence N_2O emissions, compared with synthetic fertilizers. In addition to acting as an N source, organic fertilizers provide useful nutrition supplements to the soil [e.g., organic carbon (C)]. Due to nitrification and denitrification processes, the higher C/N ratio of organic fertilizers used in paddy fields can assimilate and consume soil N, resulting in an increase in N_2O emissions. Application of organic fertilizer could change soil structure and microenvironment, thus affecting N_2O emissions as well. Similar to synthetic fertilizer, the types, amounts, and application methods of organic fertilizer have an important effect on N_2O emissions in paddy field. Combined application of organic and synthetic fertilizers is a common trend in paddy fields, but few studies have examined the interactive effect of these practices on N_2O emissions.

Others Factors

Besides water management and fertilizer application, other farming practices also affect N_2O emissions from paddy fields. Tillage and rice residue retention also have great influences on N_2O emissions in paddy fields due to changes in the soil properties (e.g., soil moisture, soil porosity, and redox potential). Generally, rice residues retention can enhance N_2O emissions. When rice residues are retained, no-till (NT) practices reduce N_2O emissions compared with plow tillage and rotary tillage during the double paddy growing season, which may be due to the increase of saturated hydraulic conductivity causing increased NH_4^+ and NO_3^- leaching under NT.^[17] There are significant differences in water and N fertilizer management under different cropping systems in the paddy ecosystem, which can lead to large variations among them. The N_2O emissions from the rice-flooding fallow cropping system are often lower than those from the rice-wheat and the double rice-wheat cropping systems due to a lower quantity of N fertilizer application and a longer flooding period. Soil texture also has a significant effect on average N_2O fluxes in paddy fields. In general, N_2O emissions from sandy soil are significantly higher than those from loam and clay soils.^[5] Such texture-induced variations in N_2O flux may be due to faster diffusion of N_2O emissions, weaker buffer action of redox potential, and lower storage capacity of organic matter in sandy soil.

MITIGATION AND CHALLENGE ON N_2O EMISSION FROM PADDY SOILS

Water management and N fertilizer application are the main factors influencing N_2O emissions from paddy soils.

Enhancement of the flooding duration can reduce N₂O emissions from paddy soils. There is a trade-off between CH₄ and N₂O emissions from paddy fields. Increases in flooding time can lead to higher CH₄ emissions, even though N₂O emissions are reduced in the paddy ecosystem. However, CH₄ emissions have a more predominant contribution to integrated and cumulative global warming potential compared with N₂O emission. Suitable late aeration may reduce N₂O emission from paddy soils, but information on its mechanism of action is scarce. Thus, it is necessary to explore appropriate water regimes to mitigate both N₂O and CH₄ emissions from paddy soils. Meanwhile, improving N fertilizer management is an easier way to mitigate N₂O emissions from paddy soils. Some cropland management options are suggested for reducing N₂O emissions from paddy fields, which include 1) changing the N fertilizer application rate; 2) choosing appropriate fertilizers types; 3) appropriate timing and precision application of fertilization; and 4) using urease and nitrification inhibitors. Adoption of other agricultural practices can reduce N₂O emissions from paddy fields through optimizing tillage practice, residues management, and cultivating rice varieties with higher N use efficiency.

Tsukuba, Japan*

Abstract

Although it has been known for more than 50 years that nitrous oxide (N_2O) is a regular constituent of the atmosphere, it was not considered to be of any importance as an air constituent until the early 1970s. Atmospheric scientists hypothesized that N_2O released to the atmosphere through denitrification of nitrates in soils and natural waters may trigger reactions in the stratosphere leading to partial destruction of ozone layer protecting the earth from biologically harmful ultraviolet radiation from the sun. N_2O is also one of the natural components of earth's atmosphere and contributes to the natural greenhouse effect; therefore, the increasing of N_2O in the atmosphere may be contributing to global warming. The atmospheric concentration of N_2O has been increasing at an accelerated rate for several decades. The global warming potential of each molecule of N_2O is about 210 times (20-year horizon) greater than each molecule of carbon dioxide.

INTRODUCTION

Although it has been known for more than 50 years that nitrous oxide (N_2O) is a regular constituent of the atmosphere, it was not considered to be of any importance as an air constituent until the early 1970s. Atmospheric scientists hypothesized that N_2O released to the atmosphere through denitrification of nitrates in soils and natural waters may trigger reactions in the stratosphere leading to partial destruction of ozone layer protecting the earth from biologically harmful ultraviolet radiation from the sun.^[1] N_2O is also one of the natural components of earth's atmosphere and contributes to the natural greenhouse effect; therefore, the increasing of N_2O in the atmosphere may be contributing to global warming.^[2]

The atmospheric concentration of N_2O has been increasing at an accelerated rate for several decades at a rate of 0.8 ppbv/yr, and the lifetime of N_2O is 120 years. It has been estimated that doubling the concentration of N_2O in the atmosphere would result in a 10% decrease in the ozone layer that would increase the ultraviolet radiation reaching the earth by 20%,^[3] eventually leading to an increase in the occurrence of skin cancer and other health problems. The global warming potential (GWP) of each molecule of N_2O is about 210 times (20-year horizon) greater than each molecule of carbon dioxide. N_2O accounts for 6% of total GWP.^[4]

THE BUDGET OF ATMOSPHERIC N_2O

Atmospheric Distribution of N_2O

As a result of biotic and anthropogenic activities, the concentration of N_2O in the atmosphere is increasing at the

rate of about 0.25%/yr. The concentration of N_2O is about 0.75 ppbv higher in the northern hemisphere than in the southern hemisphere, suggesting the presence of greater source of N_2O in the northern hemisphere than in the southern hemisphere. Ice core measurements show that the preindustrial value of N_2O was relatively stable at about 285 ppbv for most of the past 2,000 years and started to increase around the year 1700 associated with anthropogenic activity.^[4,5]

Sinks for N_2O

The major atmospheric loss process for N_2O is photochemical decomposition by sunlight (wavelengths 180–230 nm) in the stratosphere and is calculated to be 12.3 (range 9–16) Tg N/yr. Tropospheric sinks such as surface loss in aquatic and soil systems are considered to be small as compared to atmospheric sink.^[5] However, the paucity of data does not enable us to estimate the importance of this sink on a global basis.

Sources of N_2O

There are many sources of N_2O , both natural and anthropogenic, which cannot be easily quantified. Undoubtedly, the earth and oceans are significant N_2O sources. N_2O fluxes from upwelling regions of the Indian and Pacific Oceans clearly suggest that oceans may be a larger source. The ocean flux estimate is 3 (range 1–5) Tg N/yr. Tropical forest soils are probably the single most important source of N_2O emission to the atmosphere. The total N_2O emission from tropical soils (forest, savannah) is estimated at 4 (range 2.7–5.7) Tg N/yr. The magnitude of N_2O emissions from intensively fertilized tropical agricultural soils

Table 1 The amount of N₂O emission from agriculture (Mt/yr).

Mineral fertilizer	1.5 (0.5–2.5)
N-fixation	0.5 (0.25–0.75)
Soils after burning	0.1 (0.05–0.2)
Animal wastes	1.5 (0.5–2.5)
Biomass burning	0.2 (0.1–0.3)
Forest conversion	0.4 (0.1–1)
Total	4.2 (1.5–7.25)

has not been quantified. Also, no attempt has been made to separate the tropical soil sources into natural and anthropogenic components.^[5]

The main anthropogenic sources are derived from agriculture and a number of industrial processes such as adipic acid and nitric acid production. New research suggests that N₂O emissions from cropped, nitrogen-fertilized agricultural systems are significant on a global scale as shown in Table 1.

Agricultural Fields

About 40% of N₂O sources are anthropogenic and, among them, fertilized soils account for about 60%.^[5] This figure could be an underestimate because tropical agricultural soil sources resulting from human activities have not been separated from natural tropical soil sources. Agricultural N₂O emissions are considered to arise from fertilization of soils with mineral nitrogen (N) and animal manures, N derived from biological N fixation, and from enhanced soil N mineralization. N₂O is directly evolved during biomass burning, and produced in soil after burning, and enhanced emissions arise during the clearing of tropical forests for agricultural activities.^[4]

Bouwman^[6] estimated the total emissions of N₂O from a regression equation: total annual direct field N₂O–N loss = 1 + 0.0125 N application (kg N/ha). The value of 1 kg N₂O–N/ha represents the background N₂O–N evolved and the 0.0125 factor expresses for the contribution from fertilization. This estimate includes N sources from a variety of mineral and organic N fertilizers and was based on long-term data sets. About 40% of the estimated N₂O production is derived from North and Central America, Europe, and the former Soviet Union, where about 20% of the world human population resides. Asian countries that hold about 55% of the global human population contribute about 40% of the estimated annual N₂O production.^[4]

MECHANISM OF N₂O PRODUCTION

Nitrification

Nitrification is the reaction whereby ammonium is oxidized to nitrate. In soils, autotrophic and heterotrophic bacteria mediate this process. The most common ammonium

oxidizers are *Nitrosomonas* spp., which are involved in the formation of nitrite, while nitrite oxidation to nitrate is usually achieved by *Nitrobacter* spp. The overall nitrification sequence is as follows:

Two nitrogenous gases may evolve through nitrification, NO and N₂O. The nitrifiers are active over a wide range of temperatures (2–40°C). The overall nitrification process is controlled primarily by ammonium and oxygen concentrations. Because oxygen supply is moderated by soil moisture, the effect of soil water content on N transformation probably reflects its impact on oxygen diffusion in the normal soil moisture range. N₂O emissions from N-fertilizer-applied agricultural fields have been detected by Bremner and Blackmer.^[7]

Denitrification

Biological denitrification refers to the dissimilatory reduction of nitrate and nitrite to produce NO, N₂O, and N₂ by a taxonomically diverse group of bacteria which synthesize a series of reductases that enable them to utilize successively more reduced N oxides as electron acceptors in the absence of oxygen. The general reductive sequence is as follows:

The most abundant denitrifiers are heterotrophs that require sources of electron-reducing equivalents contained in available organic matter. Soil factors that most strongly influence denitrification are oxygen, nitrate concentration, pH, temperature, and organic carbon. N₂O reductase appears to be more sensitive to oxygen than either nitrate or nitrite reductase. Therefore, N₂ production predominates in more anoxic sites and N₂O production may be higher under more aerobic conditions.

Chemical Decomposition of Nitrite (Chemodenitrification)

There is evidence that nitrite produced by nitrifying or denitrifying microorganisms can also react chemically to form N₂O via “chemodenitrification.”^[8] High nitrite concentrations have been attributed to the inhibition of nitrite oxidation, which is presumed to result from ammonia toxicity to *Nitrobacter*. Several investigators have noted that gaseous loss of N (via NO, N₂O, or N₂) may accompany temporary nitrite accumulation. High concentration of nitrite is sometimes found in anaerobic soils where ammonium and ammonium type fertilizers are applied at high

doses. Nitrite ions react chemically with organic molecules forming nitroso groups ($-N=O$) that are unstable.

Other Mechanisms

Some of the N_2O evolved from soils may be formed by chemical decomposition of hydroxylamine (NH_2OH) produced by nitrifying or nitrate-reducing microorganisms, because NH_2OH has been identified as an intermediate in oxidation of ammonium to nitrate by *Nitrosomonas europaea* and has been postulated as an intermediate in microbial reduction of nitrate to ammonium, and several investigations have shown that NH_2OH is decomposed rapidly in soils with formation of N_2O and N_2 by processes that appear to be largely chemical. Other investigations indicated that manganese compounds are involved in the reactions leading to the formation of N_2O and N_2 by chemical decomposition of NH_2OH in soils, and that calcium carbonate and iron compounds are involved in the reactions leading to formation of N_2 in calcareous soils. The reaction is as follows:

Several workers^[1] have postulated that N_2O is produced in soils through interaction of hydroxylamine and nitrite produced by soil microorganisms as follows:

MEASUREMENT OF N_2O EMISSION

N_2O emissions from N-fertilized agricultural fields have been found to vary between 0.001% and 6.8% of the N applied to the field.^[9–11] A proportion of this variability in N_2O estimates, relative to the amount and type of fertilizer applied and to the type of cropping system such as grassland, upland crop, rice paddy, and others, has been attributed to spatial and temporal change in the processes, which produce N_2O in soil.

MITIGATION STRATEGY

Many of the strategies were proposed by Mosier et al.^[12] 1) match N supply with crop demand; 2) close N flow cycles; 3) use advanced fertilizer technologies; and 4) optimize tillage, irrigation, and drainage, in which gaseous emissions that deal primarily with cropping systems could be minimized. Although most of the practices listed are assumed to decrease N_2O emissions, there have been relatively few systematic studies in which various farming practices were compared as to their ability to conserve N and limit N_2O emissions. A number of field studies have been conducted with nitrification inhibitors that could decrease N_2O emissions when used. There are a few studies

in which the potential of using controlled-release fertilizer for decreasing N_2O emission was evaluated as follows.

Nitrification Inhibitors

Because ammonia- and ammonium-producing compounds are the main sources of fertilizer N, maintenance of the applied N in the ammonium form should result in a lower emission of N_2O from cultivated soils. One mechanism of maintaining added ammonium N is to use nitrification inhibitors with the fertilizer. Mosier et al.^[12] summarized the effects of nitrification inhibitors on N_2O emission from fertilized soils both in laboratory and field studies. A number of field studies indicate that nitrification inhibitors do limit N_2O emissions from ammonium-based fertilizers. Several field tests also show that the utilization of a variety of nitrification inhibitors does significantly limit N_2O emissions from the application of ammonium-based fertilizers. To illustrate this point, a study to quantify the effect of nitrification inhibitors N-(2, 5-dichlorophenyl) succinamic acid (DCS) and the application of ammonium sulfate on N_2O emissions was conducted in field lysimeters using carrot (*Daucus carota* L.) as a test crop.^[11] The addition of DCS reduced about 30% of N_2O emission and leaching of nitrate.

Controlled-Release Fertilizer

The use of controlled-release fertilizer has the potential to improve N-use efficiency by matching nutrient release with crop demand, reducing NO_3^- leaching, and denitrification losses. Polyolefin-coated fertilizers are a type of controlled-release fertilizer where fertilizer granules are covered with a thermoplastic resin. The release of the N fertilizer is temperature dependent and is not controlled by hydraulic reactions or by microbial attack of the coating. Greenhouse studies have revealed that controlled-release fertilizer can increase yields with more N-fertilizer use efficiency and reduce NO_3^- leaching.

For example, Minami^[11] observed that a controlled-release fertilizer reduced N_2O emissions in lysimeter studies of carrot at Tsukuba, Japan, in which the fertilizer-induced emissions of N_2O-N during an 83-day period of cultivation were 0.14% and 0.02% of the 250 kg N applied following ammonium sulfate and a controlled-release fertilizer, respectively.

No Till

Paul W. Unger

Conservation and Production Research Laboratory, U.S. Department of Agriculture (USDA), Bushland, Texas, U.S.A.

Abstract

Conservation tillage and no-till farming systems are based on retaining sufficient crop residues on the soil surface, mainly to control erosion. Other benefits include greater water conservation; improved environmental protection; equipment, energy, and labor savings; and often greater net returns to the producer. Some disadvantages that occur under some conditions and the systems, especially no-till, may not be suitable for all conditions. Most disadvantages, however, can be overcome or minimized by careful management.

INTRODUCTION

No-till, also known as no-tillage or zero-tillage, is a type of conservation tillage, which is a planting system that results in at least 30% cover of crop residues on the soil surface after planting the next crop.^[1] Use of conservation tillage provides major soil erosion control benefits and also helps conserve water. In contrast, conventional tillage refers to tillage operations normally used for crop production that bury most residues and result in <30% cover of residues on the soil surface after planting. Tillage that incorporates all residues into soil is clean tillage. Conventional and clean tillage are less effective for controlling erosion and conserving water than conservation tillage under many conditions.

Tillage methods such as sweep, chisel, paraplow, subsoiling, slit, and strip rotary usually qualify as conservation tillage. Even disk tillage may qualify, provided adequate residues are retained on the surface. The ultimate conservation tillage method is no-till for which the next crop is planted without any soil disturbance since harvesting the previous crop. A special planter is usually needed to prepare a narrow, shallow seedbed for the seed, which is planted by the no-till method.^[1] Sometimes, no-till is used in combination with a subsoiling operation that facilitates crop seeding and plant root growth but that leaves the surface residues virtually undisturbed, except for the slot caused by the subsoiling implement.^[1]

Adequate residues are not always produced to provide 30% cover [e.g., dryland (non-irrigated) crops]. Also, a crop such as cotton (*Gossypium hirsutum* L.) may not produce enough residues under some conditions to satisfy the required ground cover for conservation tillage. Under such conditions, some conventional or even clean tillage methods can provide for soil and water conservation. Any tillage method that results in a rough or ridged surface helps reduce soil erosion by wind. Listing (ridge-forming tillage)

is commonly used to help control wind erosion in the cotton-producing area of west Texas, U.S.A., where residue amounts are usually low (personal observation). Even plowing, which brings erosion-resistant clods to the surface, helps control wind erosion on some sandy soils.^[2] Any tillage method that impedes or prevents water flow across the surface helps reduce soil erosion by water and usually helps conserve water. Listing on the contour retains water on the surface, thus reducing erosion and conserving water. Furrow diking in conjunction with listing improves water retention where contour tillage is not used.^[3] Graded-furrow tillage allows excess water to flow slowly from land, thus reducing the potential for erosion; it also provides water conservation benefits.^[4]

ADVANTAGES AND DISADVANTAGES OF USING CONSERVATION TILLAGE AND NO-TILL

Compared with clean tillage, advantages of different conservation tillage types, including no-till, include improved erosion control, a cleaner environment, greater water conservation, equal or greater crop yields, less equipment and lower maintenance costs, lower energy and labor requirements, and greater net returns. Erosion control benefits from conservation tillage are due to more residues being retained on the soil surface. For controlling erosion by wind, residues shield the surface and reduce wind speed at the surface to below the threshold required for erosion to occur. Erosion by water is reduced because residues reduce the rate and amount of water flow across the surface. Residues also result in less soil particle detachment and transport due to raindrop splash and flowing water. The value of surface cover provided by crop residues for controlling erosion by wind and water is shown in Fig. 1.^[5]

Fig. 1 Relationship of the soil loss ratio (soil loss with cover divided by soil loss from bare soil).

Source: From Papendick, Parr, et al.^[5]

Water conservation with conservation tillage results from residues retarding the rate of water flow across the surface, thus providing more time for infiltration. Residues also shield the surface against raindrop impact, thus dissipating the energy of raindrops, reducing surface sealing, and maintaining favorable infiltration rates. Residues reduce soil water evaporation by shading the soil and slowing the wind at the soil surface. Of course, the soil must have adequate storage capacity for the water to be retained for later use by crops.

Use of conservation tillage reduces erosion, thus resulting in a cleaner environment. Erosion by wind damages crops, causes health and visibility problems, clogs roads and waterways, damages machinery and homes, and pollutes the air. Erosion by water damages crops, roads, machinery, and homes. It also pollutes water with soil particles, chemicals adhering to the particles, and chemicals dissolved in water.

Crop yields are affected by numerous factors. Yields with conservation tillage systems are often greater than with clean tillage, provided no major problems are encountered. Increase in yield, especially with no-till, is usually attributable to greater soil water conservation, especially in subhumid and semiarid regions without irrigation. More favorable soil temperatures may also be involved. In warm or hot regions, high soil temperatures may injure plants, and surface residues with no-tillage result in temperature decreases of up to 10°C,^[6,7] which result in better crop performance. In cool regions, low temperatures with no-till are usually detrimental to crop yields because planting is delayed beyond the optimal date.^[8]

Advantages of lower equipment inventories, equipment maintenance, and energy and labor requirements with conservation tillage are interrelated. With most conservation tillage methods, and especially no-till, tillage frequency and intensity are lower than with clean tillage. As a result, less equipments may be needed, smaller tractors may be satisfactory (for no-till), and the tractors and equipments are used less frequently. This results in less equipment

maintenance and in lower fuel and labor requirements. Some fuel energy savings, however, may be partially offset by the energy required to produce herbicides and fertilizer, especially where no-till is used. The no-till system is based on using herbicides for weed control, and more nitrogen fertilizer is used under some conditions, especially when first converting to the system.

As for yields, many factors affect net returns for a crop production system. However, if production costs are not greater and yields are equal to or exceed those with clean tillage, then net returns should be equal or greater with conservation tillage, especially with no-till, because equipment inventories and maintenance and labor and energy requirements are lower.^[9,10]

Disadvantages

Problems with conservation tillage, especially no-till, occur under some conditions.^[8,11–13] A greater use of herbicides results in concern regarding the potential for polluting soil and water resources. Lower soil temperatures in cool regions delay crop planting, thereby potentially reducing crop yields. On poorly drained soils, additional water retained by using no-till aggravates the excess soil water problem, thus generally reducing crop yields. Some weeds are difficult to control with herbicides, which, along with the high cost of some herbicides, may increase production costs. The possible need for new equipment may also increase production costs, especially when first converting to a no-till system. Because crop residues are retained on the surface when a no-till system is used, there is the potential for increased pest problems (insects, diseases, and rodents). Problems are greater with some insects and less with others, indicating that insect populations must be closely evaluated regardless of tillage system used. Organisms of some plant diseases are carried over to the next crop when residues are retained on the soil surface. Surface residues also provide shelter for rodents, which may be detrimental for the production of some crops. Other possible disadvantages include limited residue availability, greater soil compaction, and a need for greater managerial ability. Certainly, conservation tillage and no-till are not suitable for all conditions. However, with good management, most problems (real or potential) can be minimized or avoided.

RESULTS ACHIEVED BY USING CONSERVATION TILLAGE OR NO-TILL

The value of conservation tillage and no-till farming methods for controlling erosion, conserving water, and increasing crop yields has been shown in numerous studies, but only a few examples will be given here. Probably, the most dramatic example regarding the value of no-till for controlling erosion occurred during a rainstorm on watersheds

planted with corn (*Zea mays* L.) in Ohio, U.S.A.^[14] Treatments were clean tillage with sloping rows (land slope 6.6%), clean tillage with contour rows (land slope 5.8%), and no-till with contour rows (land slope 20.7%). On the respective treatment areas, rainfall was 140, 140, and 129 mm; runoff was 112, 58, and 64 mm; and sediment loss was 50.7, 7.2, and 0.07 Mg/ha. Even though the slope was much greater, soil loss was negligible from the no-till area. Runoff was also low, which provided an opportunity to store more soil water, but soil water information was not given.

Soil losses determined by using a rainfall simulator averaged 2.1 and 5.7 Mg/ha where no-till and conventional tillage, respectively, were used for wheat (*Triticum aestivum* L.) and soybean (*Glycine max* L.) production in Paraná, Brazil. Losses from bare soil averaged 100.2 Mg/ha during the same period.^[15] No-till is widely used to control soil losses in Brazil^[16] and Paraguay (personal observations). Crop residues retained on the soil surface by using no-till was highly effective for reducing runoff and soil losses on Oxisols in Brazil.^[17]

Rainfall totaled 346 mm in July and August 1992 in Australia. Runoff from an Alfisol averaged 136 mm from bare soil where no-till, shallow tillage, and deep tillage treatments were imposed, but only 4 mm with the same treatments when the soil was covered by straw.^[18] As a result, water storage was much greater in the straw-covered soil. The infiltration of water (simulated rainfall at 108 mm/hr for 20 minutes) was greater (less runoff) in Queensland, Australia, when a clay soil was treated with gypsum or when a surface cover of wheat straw was present. With gypsum applied at 0 (check), 2, and 5 Mg/ha, cumulative infiltration was 12%, 37%, and 50%, respectively, with no surface cover, and 45%, 68%, and 76%, respectively, with an 80% surface cover.^[19] The residue cover was more effective than gypsum for enhancing infiltration, thereby improving soil water conservation for crop production. Retaining crop residues on the soil surface by using no-till was found to be effective for increasing water storage in soil in other studies in Australia.^[20,21]

In India, soil water conservation and crop yield increases occurred when plant residues were placed on the soil surface as a mulch.^[22,23] Applying the mulch soon after plant emergence was the most effective treatment.^[23] Similar results should occur by using no-till, provided adequate residues retained on the soil and weeds are effectively controlled. In some studies in India, however, weed control with no-till was not as good as with plowing^[24] or hand weeding,^[25] which resulted in lower crop yields with no-till. Effective weed control is a prerequisite for successful crop production with no-till.

After harvesting irrigated winter wheat, moldboard, rotary, disk, sweep, and no-till treatments were imposed to manage the residues during the fallow period until planting dryland grain sorghum [*Sorghum bicolor* L. (Moench)] 10–11 months later at Bushland, Texas, U.S.A. Weed control was similar with all treatments. Plant-available soil water

contents averaged 149, 143, 158, 179, and 207 mm at sorghum planting and sorghum grain yields averaged 2.56, 2.19, 2.37, 2.77, and 3.34 Mg/ha with the respective treatments. Greater water contents and yields with conservation tillage (sweep and especially no-till) resulted from the retention of more residues on the surface than with other treatments. The presence of residues resulted in greater infiltration and lower evaporation, but the effect of the different processes could not be determined.^[26]

A field study at Akron, Colorado, U.S.A., clearly showed the value of surface residues with conservation tillage (minimum and no-till) for reducing evaporation. Soil water contents one day after 13.5 mm rain were similar to a depth of 15 cm where conventional, minimum, and no-tillage treatments were imposed after harvesting winter wheat. The treatments resulted in 1.2, 2.2, and 2.7 Mg/ha of surface residues, respectively. After 34 rainless days, the soil had dried to $<0.1 \text{ m}^3/\text{m}^3$ water content at depths of 12, 9, and 5 cm, respectively.^[27] The value of surface residues for reducing evaporation was also shown under laboratory conditions.^[28,29]

CONCLUSION

Conservation tillage and no-till farming systems are based on retaining sufficient crop residues on the soil surface, mainly to control erosion. Other benefits include greater water conservation; improved environmental protection; equipment, energy, and labor savings; and often greater net returns to the producer. Some disadvantages that occur under some conditions and the systems, especially no-till, may not be suitable for all conditions. Most disadvantages, however, can be overcome or minimized by careful management.

Nutrient Management

Jorge A. Delgado

Soil Plant Nutrient Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Fort Collins, Colorado, U.S.A.

Abstract

Nutrient management has been defined as “the science and art directed to link soil, crop, weather, and hydrologic factors with cultural, irrigation, and soil and water conservation practices to achieve the goals of optimizing nutrient use efficiency, yields, crop quality, and economic returns, while reducing off-site transport of nutrients that may impact the environment.” Nutrient management, together with soil and water conservation practices, will be key to adapt to the challenges of the 21st century. We need to apply the right amount of fertilizer at the right place at the right time with the right fertilizer sources (4 Rs) and also incorporate the right conservation practices to increase conservation effectiveness, improve nutrient use efficiency, and reduce the transport of nutrients from the farm and across the landscape; this is the 7 Rs of nutrient management and conservation.

INTRODUCTION

“Nutrient management is the science and art directed to link soil, crop, weather, and hydrologic factors with cultural, irrigation, and soil and water conservation practices to achieve the goals of optimizing nutrient use efficiency, yields, crop quality, and economic returns, while reducing off-site transport of nutrients that may impact the environment.”^[1] Although this sounds like a simple task, it is very difficult to work with natural agroecosystems and spatial variability of soil, including variabilities in soil chemical, physical, and biological properties. These variabilities together with temporal and spatial variabilities of weather (e.g., temperature, precipitation, etc.) influence plant physiological responses as well as responses from weeds, pests, and diseases that could also impact crop yield and quality. Even the management of nutrients at a site-specific location and how the field is managed in a given year, will impact the cycling of nutrients and/or residual nutrients in a given year, impacting nutrient availability and yield responses in the following year. The crop rotation, the use of a cover crop, applications of manures, and how the soil is tilled are examples of management practices that will impact the soil biological, physical, and chemical properties and nutrient cycling and management in the following year.

Nutrient management is not a simple task; even management practices that may reduce losses of a nutrient via one pathway (e.g., volatilization and surface runoff) may increase losses of the same nutrient or another nutrient via another pathway (e.g., leaching). Nutrient management is a skillful task of matching the nutrient demands of a crop with the nutrient sources during the growing season considering site-specific field soil properties, the site-specific climate, and site-specific crop management practices. With

that said, nutrient management is key for agricultural production and for food security and global stability, since supplying and/or managing essential crop nutrients is an important way to increase yields and crop quality and contribute to economically viable systems.

NUTRIENT MANAGEMENT IS KEY FOR ADDRESSING GLOBAL CHALLENGES

There are several global challenges that are creating a need for significant increases in worldwide agricultural production per unit area, and nutrient management will be essential to supply adequate amounts of essential nutrients that are needed to increase and sustain these desired higher yield responses to meet global food demands. One of the main challenges driving this need for higher yields is the continuously increasing world population. It is anticipated that within the next few decades, we will have to increase agricultural production by 70% to feed the additional two billion people that it has been projected the world population will have by 2050.^[2] Another challenge related to this projected increase in population by two billion people is that it is anticipated that the demand for higher protein diets will increase in the next few decades due to higher consumption of protein from livestock and dairy products.^[3]

A changing climate with extreme events is another challenge that can impact agricultural production and how we manage nutrients. For example, reports suggest that a changing climate could potentially have a negative impact on agricultural production by 2050 or 2100 due to extreme events such as droughts and/or flooding,^[4] higher temperatures, and potential negative impacts on soil erosion^[5] that could contribute to reduced yields. Fortunately, we could

use nutrient management and conservation practices to contribute to mitigation of and adaptation to the negative effects of a changing climate and extreme events.^[6] However, under conditions of extreme drought, there may be limitations to adaptation capabilities.^[6,7] Water is the most important nutrient and a limiting factor for maximum yields, and under extreme events (droughts), there may be lower potential for adaptation.

Another global challenge is the depletion of water resources, which are so important for maintaining agricultural production across key worldwide agroecosystems.^[4] Some of the most productive worldwide agroecosystems depend on available irrigation water resources. For these regions, irrigated agriculture on average can have twice the yields of nonirrigated agriculture.^[8] Nutrient management in irrigated agriculture is an important component of the challenges being faced, and nutrient managers need to consider the hydrologic cycle when managing nutrients to ensure that management contributes to meeting the higher nutrient demands during the growing season as well as to minimizing the higher potential for nutrient losses via leaching and/or off-site surface transport from potential irrigation erosion and/or surface water runoff. Nutrient management will be important and may change with the different irrigation systems used for each respective region (e.g., surface irrigation, sprinkler irrigation, and drip irrigation). Different irrigation systems could be applied, or in some cases, farmers may even incorporate limited irrigation management practices depending on the year and availability of water for the region.

Nutrient management will be a key part of efforts to adapt to changes in water resources.^[6] Other examples of global challenges that may impact agricultural production systems are desertification, deforestation, salinization, and energy resources. Responses to these challenges and others will have to include nutrient management plans at the site-specific region. Global challenges will likely impact management practices at a given site, and the management responses for crops, forages, and agroforestry systems will need to include nutrient management plans to maximize agricultural production and economic returns at a given site.

NUTRIENT MANAGEMENT AND ENVIRONMENTAL CHALLENGES

Nutrient management is key for increasing yields; however, when nutrients are applied at higher rates than necessary or when they are not managed using the best management practices recommended for a given management-landscape combination, the potential for losses of nutrients to the environment increases. These losses could significantly contribute to environmental challenges. It has been reported that the increase in use of nitrogen inputs has

contributed to increased losses of reactive nitrogen. Adding nitrogen to agricultural systems increases the probability of higher rates of nitrogen losses from the nitrogen cycle as ammonia, ammonium, nitrogen oxides, nitrous oxide, and nitrate (NO_3); these nitrogen compounds are all reactive forms of nitrogen.^[9]

The excess application of these nutrients could contribute to higher losses that could significantly impact the function of terrestrial, freshwater, and marine ecosystems, including impacts to quality of groundwater resources.^[9–11] Several reports in the literature about the effects of nutrient losses have listed different impacts to air, soil, and water quality. These environmental impacts are reported to contribute to lower pH of forest soils, resulting in acidification. Other negative impacts can include poor water quality conditions that can have negative societal impacts due to eutrophication of aquatic ecosystems, hypoxia in freshwater and coastal areas, harmful algae blooms, and contamination of drinking water (surface and groundwater) resources with NO_3 concentrations above levels considered safe for consumption. Impacts to air quality from nutrient losses can have negative effects on society such as odors and contributions to trace gas emissions (e.g., nitrous oxide) that are reported to contribute to climate change.^[4] The scientific literature shows that nutrients are critical for food security and societal stability; however, it also shows that nutrient management must be used to reduce the environmental challenges created due to their intensive use, in order to minimize nutrient losses and their potential negative impacts to air, soil, and water quality.

The loss of nitrogen from fields contributes to an effect known as the nitrogen cascade, where the environmental impacts are multiplied as the reactive nitrogen is cycled through the environment and contributes to additional losses of reactive nitrogen.^[9] Accumulations of these nutrients (e.g., phosphorous) could also contribute to legacy effects where negative impacts are increased several years after continued increases in the soil content, to the point that the losses are significantly increased.^[11] Fortunately, nutrient management, together with conservation practices, can help minimize the losses of nutrients and minimize these environmental challenges.^[12] Delgado^[12] reported that there is a need to increase the communication between nutrient managers and conservation practitioners to increase nutrient use efficiencies at the farm level while reducing the off-site transport of nutrients.

KEEPING UP WITH ADVANCES IN NUTRIENT MANAGEMENT

New technological advances in software, electronics, and engineering that are applied to the field of nutrient

management are continually being developed, and nutrient managers need to keep up with these advances that can potentially contribute to higher yields and nutrient use efficiencies and to reduced nutrient losses to the environment. Specifically, advances in remote sensing, field sensors, unmanned aerial vehicles, drones, computer models, nutrient indexes, geographic information systems, mobile phones, and new nutrient management apps are examples of areas where new technologies are achieving significant advances that are being applied for nutrient management and/or have nutrient management implications. A large number of these advances in nutrient management are being driven by advances in linking and/or managing databases on soils, crops, weather, and hydrological properties for quick integration and analysis of information to develop improved management decisions.

More and more, these advances are also integrating spatial and temporal properties in their analysis. The accessibility of the Internet and a faster flow of information have been contributing to the integration of these large databases to provide quick analysis and recommendations at the field level and on the go as machinery is moving across the field. Advances of mobile technologies, such as smartphones that can connect to the cloud quickly, in combination with new, advanced phone apps, are facilitating the flow of information and helping users make decisions from wherever they are. By integrating the information from “big data” quickly, nutrient managers can make decisions on the go and respond to nutrient

management needs. The capabilities of global positioning systems are also allowing the development of highly accurate maps (within a few centimeters), and the controls and sensors of new nutrient management/agricultural machinery are helping nutrient managers improve management decisions to increase nutrient use efficiencies on the go. There are several private sector companies that are expanding these capabilities to allow farmers and nutrient managers to integrate yield maps and remote sensing maps with nutrient analysis maps to develop improved management recommendations. An example is the John Deere Mobile Farm Manager software applications.^[13] These apps can help save information on where soil samples were collected in the field, access field information, and share the information with trusted advisors or export information to models. This is just an example and there are several other private industry apps and new software that are being used by consultants, service providers, nutrient managers, extension personnel, and farmers.

Spatial variability of nutrients across the field can be monitored with these new technologies, and we can use precision farming to improve management of nutrients and reduce nutrient losses to the environment.^[14,15] We could use these new technologies to apply variable rates to better match the rate of nutrient application with the rate of nutrient uptake across the field during the growing season, thus improving nutrient use efficiencies and reducing nutrient losses.^[14,15] Or, we could divide the field into management zones and manage this spatial

Fig. 1 The site-specific approach can be expanded to a 3-D scale approach that assesses inflows and outflows from fields to watershed and region scales.

Source: From Berry, Delgado, et al.^[16] ©2003 Journal of Soil and Water Conservation.

variability by areas of the field to better improve the nutrient sources for a given subarea of the field, matching the average nutrient uptake in the zone with the average nutrient source per zone during the growing season.^[17] Sensors are tools that can help provide *in situ* rapid evaluations of the nutrient status of a field to manage this spatial variability and integration of information across the field to improve nutrient management decisions.^[14,15]

NEED FOR A JOINT NUTRIENT MANAGEMENT AND CONSERVATION APPROACH TO INCREASE EFFICIENCY AND REDUCE ENVIRONMENTAL LOSSES OF NUTRIENTS

Even with the advances as far as integrating large databases of information to improve nutrient management and apply the right amount of fertilizer at the right place at the right time with the right fertilizer sources (4 Rs),^[18] there is a need to also incorporate the right conservation practices using precision information to increase conservation effectiveness, improve nutrient use efficiency, and reduce the transport of nutrients out of a farm and across the landscape.^[12] Delgado reported that the 4 Rs for nutrient management alone are not enough to reduce nutrient losses. The 4 Rs alone do not integrate variable information about how to maintain and/or improve soil health and soil quality, or how to increase soil carbon sequestration, or how to reduce erosion to maintain soil sustainability and soil health at the site-specific location.

Practices that maintain and/or improve soil health and quality, increase soil carbon sequestration, or reduce erosion will impact nutrient availability and cycling at a given site and should be part of the decision process of site-specific nutrient management but they are not part of the 4 Rs decision process.^[12] Additionally, even if the 4 Rs are applied at a site-specific field, due to the spatial and temporal variability of weather, soils, and crops, the potential for NO_3 losses could be significantly high unless precision conservation practices are implemented across the field, farm, and landscape to minimize the transport of nutrients. For example, the 2012 drought reduced yields significantly across large regions of the Midwest, significantly reducing the potential for nitrogen uptake and increasing the potential for NO_3 leaching losses.^[7] This is an example of the need for and potential of incorporating precision conservation practices at a field level and across farms and the landscape to reduce the potential for nutrient losses.^[12,16,19] There is a need to bring crop advisors and nutrient managers together with soil and water conservation practitioners to increase application of precision conservation so we can increase nutrient use efficiencies at a farm level while reducing the transport of nutrients across the farming landscape and natural areas (Figs. 1–3).

Fig. 2 One possible conservation planning scenario for Lime Creek.

Source: From Tomer, Porter, et al.^[19] ©2013 Journal of Soil and Water Conservation.

Precision conservation was defined as a set of spatial technologies that accounted not only for the spatial variability across the agricultural systems but also through the natural areas outside of the field. Precision conservation analysis could help connect the flows of nutrients from site-specific fields to surrounding landscape areas where buffers, riparian zones, wetlands, and forests could be applied to reduce the transport of these flows.^[16,19] It has been reported that a precision conservation approach could contribute to the management of nutrients while they are in the farm to help reduce movement of nitrogen and other chemicals across the landscape of a farm and natural areas.^[12] It has also been reported that “if we are to increase conservation effectiveness and nutrient use efficiency and minimize the losses of sediment and nutrients to the environment, we need to apply the right product (fertilizer), at the right fertilizer rate, with the right method of fertilizer application, with the right conservation practice, and with conservation practice at the right place, and at the right scale of conservation practice, with both the fertilizer and the conservation practice applied at the right time (right product, right rate, right method, right practice, right place,

Fig. 3 Effects of organic carbon on nutrient cycling and productivity.

right scale, and right time: the 7 Rs of nutrient management and conservation).”^[12]

CONCLUSION

Nutrient management has been defined as “the science and art directed to link soil, crop, weather, and hydrologic factors with cultural, irrigation, and soil and water conservation practices to achieve the goals of optimizing nutrient use efficiency, yields, crop quality, and economic returns, while reducing off-site transport of nutrients that may impact the environment.”^[1] Nutrient management will be one of the most important tools in efforts to achieve food security during the 21st century and feed the increasing population with growing demand for higher protein diets. At the same time, improved nutrient management will also contribute significantly to addressing other environmental challenges of the globe by reducing losses of nutrients to the environment.

Nutrient management technologies are being developed in the world to allow for rapid analysis of large databases for precision farming, but the best pathway ahead to increase nutrient use efficiencies and minimize the losses of nutrients involves incorporation of precision conservation to increase conservation effectiveness across the landscape for air, soil, and water quality. In areas where these new technologies are not being used, other basic principles of nutrient management can be applied to increase nutrient use efficiencies while increasing air, soil, and water conservation.

There is a need to increase communication and cooperation between nutrient managers and conservation practitioners to implement a 7 Rs approach to apply the “right

product, right rate, right method, right practice, right place, right scale, and right time: the 7 Rs of nutrient management and conservation” to maximize nutrient use efficiencies, decrease losses of nutrients to the environment, and reduce their transport across the landscape.^[12]

Nutrient Management: Fertility and

John L. Havlin

Department of Soil Science, North Carolina State University, Raleigh, North Carolina, U.S.A.

Abstract

Future population growth will drive increased food and fiber production per unit of land. Increasing crop productivity increases soil nutrient removal and the importance of replenishing soil fertility through effective and efficient nutrient management. Native soil nutrient supply depends on the soils' ability to buffer nutrient loss through crop removal. Mineralization of soil organic fractions provides limited supplies of nitrogen, sulfur, and micronutrients, while mineral dissolution and surface exchange reactions resupply phosphorus, potassium, calcium, magnesium, and micronutrients. Nutrient mobility in soil influences ion transport to plant roots, the evaluation of nutrient availability to plants, and ultimately nutrient management decisions. Effective nutrient management requires quantifying crop nutrient requirement and the nutrient supplying capacity of the soil through soil testing. Once these are determined, the nutrient management plan includes the determination of optimum nutrient rate, appropriate nutrient source(s), most effective nutrient placement method(s), and nutrient application timing. Management decisions will vary depending on the specific nutrient. Effective management of soil nutrients will ensure crop productivity meet consumption demand, while minimizing impacts of nutrient use on the environment.

INTRODUCTION

Nutrients are essential to support life and are acquired through diverse food sources, ultimately supplied by the soil. While plants are a major direct human food source, animals used as human food also obtain nutrients from a variety of plants (forage and grains) in their diets. As plants are consumed or removed from a field, the nutrients are also removed. With continued crop removal over time, soil nutrients are depleted and plant productivity declines. As food demand increases with increasing population growth, a greater agricultural output demand requires substantial replacement of soil nutrients through the addition of inorganic fertilizers and organic wastes. Therefore, to optimize nutrient availability to crops and to minimize environmental risk of nutrient use, it is essential to understand nutrient reactions and processes in soils (*soil fertility*) and to efficiently manage nutrient inputs (*nutrient management*) to ensure adequate soil nutrient supply to support life. Without effective management of soil nutrients, 30–40% more land area will be needed to produce the same crop yields depending on the crop, soil, and climatic region. Therefore, crop producers must take advantage of technologies that increase productivity as well as those that minimize productivity loss.

SOIL FERTILITY

Soil fertility represents the diverse interactions between physical, chemical, and biological soil processes that control plant nutrient supply. Understanding these processes

and interactions is critical to optimizing nutrient availability to crops. Maximum crop production depends on the growing season environment and the producers' skill to minimize yield-limiting factors using appropriate management technologies. Crop productivity is maximized when the *most* limiting factor to yield potential is corrected first, the second most limiting factor next, and so on (*Law of the Minimum*). For example, the correct nutrient supply may not result in the highest yield potential if plant-available water (H₂O) is the *most* limiting factor. Thus, minimizing H₂O as a yield-limiting factor must be accomplished before the crop can fully respond to management of any other factor.

Essential Plant Nutrients

Seventeen elements are considered essential plant nutrients since they are involved in metabolic functions such that the plant cannot complete its life cycle without these elements (Table 1). The most abundant non-mineral nutrients (carbon, hydrogen, and oxygen) are obtained from carbon dioxide (CO₂) and H₂O and converted into carbohydrates that form amino acids, proteins, nucleic acids, and other compounds through photosynthesis. The supply of CO₂ has increased from ~310 to 390 ppm CO₂ since 1960. The supply of H₂O rarely limits photosynthesis directly but reduces plant growth when plant-available H₂O is limited. The remaining 14 macronutrients and micronutrients are classified on their relative abundance in plants. The nitrogen (N) concentration in most plants is greater than the

Table 1 Essential plant nutrients and their relative and average concentration.

Classification	Nutrient		Concentration in plants ^a	
	Name	Symbol	Relative	Average
Macronutrients	Hydrogen	H	60,000,000	6%
	Carbon	C	40,000,000	45%
	Oxygen	O	30,000,000	45%
	Nitrogen	N	1,000,000	1.5%
	Potassium	K	250,000	1.0%
	Calcium	Ca	125,000	0.5%
	Magnesium	Mg	80,000	0.2%
	Phosphorus	P	60,000	0.2%
	Sulfur	S	30,000	0.2%
	Chloride	Cl	3,000	100 ppm
Micronutrients	Iron	Fe	2,000	100 ppm
	Boron	B	2,000	20 ppm
	Manganese	Mn	1,000	50 ppm
	Zinc	Zn	300	20 ppm
	Copper	Cu	100	6 ppm
	Nickel	Ni	2	<1 ppm
	Molybdenum	Mo	1	<1 ppm

^aConcentration expressed on a dry matter weight basis.

other 13 nutrients combined. Although nutrient content varies greatly between plant species, most plants also require substantial amounts of calcium (Ca) and potassium (K; Table 1). Plants absorb many non-essential elements present in the soil solution. For example, aluminum ions (Al^{3+}) in plants can be high when soils contain relatively large amounts of soluble Al (low pH soil). In some severely acid soils, Al toxicity can reduce plant growth and yield. In high-pH soils, sodium ion (Na^+) can be elevated in soil solution and/or on the exchange complex, increasing Na^+ in the plant, which can also be detrimental to plant growth.

Many soil, climate, and management factors influence plant nutrient availability. When nutrient concentration is *deficient* enough to severely reduce plant growth and yield, distinct visual deficiency symptoms appear (Fig. 1). Extreme deficiencies can result in plant death. Visual symptoms may not appear when a nutrient is marginally deficient (*hidden hunger*), but plant yields may still be reduced. Plant nutrient concentration above which plant growth or yield is not increased is the *critical level* or *range*. Critical nutrient ranges vary among plants but always occur in the transition between nutrient deficiency and sufficiency (Fig. 1). *Sufficiency* or *luxury consumption* is the concentration range, where added nutrient does not increase yield but increases nutrient concentration. Nutrient concentration is considered *excessive* or *toxic*, when plant growth and yield are reduced.

Fig. 1 Optimum nutrient supply is essential for maximizing plant growth and nutrient use. Nutrient addition beyond critical nutrient range does not increase plant growth.

Soil Processes Supplying Plant-Available Nutrients in Soil

After plants absorb nutrients from soil, nutrients are exported in harvested plant materials or returned to soil in plant residues left in the field. These nutrients are subject to the same biological and chemical reactions as nutrients added as fertilizers and organic wastes. Although this “cycle” varies among nutrients, understanding nutrient dynamics in the soil–plant–atmosphere system is essential to successful nutrient management.

As plants absorb nutrients from soil solution, reactions occur to resupply the soil solution (Fig. 2). These reactions

Fig. 2 Primary processes of buffering nutrients in soil solution absorbed by plant roots. Clay minerals (cation/anion exchange), OM (mineralization), and mineral compounds (dissolution) resupply nutrients to soil solution, as they are removed from solution by plant uptake.

Source: From Barker & Pilbeam,^[1] Grant & Milkha,^[2] and Havlin, Tisdale, et al.^[3]

are important to nutrient availability; however, the dominant reaction varies between nutrients. For example, biological processes are more important for N and sulfur (S) availability, and surface exchange reactions are important for Ca, magnesium (Mg), and K supply to roots.

Cation and anion exchanges

Exchange of cations and anions on surfaces of clay minerals, inorganic compounds, organic matter (OM), and roots is one of the most important soil chemical properties and greatly influences nutrient availability (Fig. 2). Ions adsorbed on mineral and organic surfaces are reversibly exchanged with other ions in the solution. *Cation exchange capacity* (CEC) represents the quantity of negative (–) charge available to attract cations in solution, and the *anion exchange capacity* (AEC) represents positive (+) charge attracting anions in a solution. In most soils, CEC is greater than AEC.

The source of (+) or (–) surface charges found in clay minerals is comprised of permanent charge unaffected by solution pH, and on (+) and (–) charges located on clay mineral edges and soil OM (Fig. 3).

At low pH, more (+) charge exists due to higher hydrogen ions (H^+) on mineral edges and OM; as pH increases, H^+ concentration decreases, which increases (–) edge or surface charge. At $pH > 7$, all H^+ on edges are neutralized, which maximizes (–) pH-dependent charge (Fig. 3). Soils with greater clay and OM contents have a higher CEC than sandy, low OM soils (Table 2).

CEC influences nutrient availability, as most adsorbed cations are essential plant nutrients, except for Al^{3+} in acid soils and Na^+ in alkaline pH soils. Cations are adsorbed into CEC with different strengths, which influence the relative ease of desorption. The *lyotropic series*, or relative strength of adsorption, is Al^{3+} (H^+) > calcium ions (Ca^{2+}) > magnesium ions (Mg^{2+}) > potassium ion (K^+) = ammonium ion

Table 2 Typical range in CEC for moderately weathered (Mollisol) and highly weathered (Ultisol) soils.

Soil textural class	Mollisol	Ultisol
	(cmol kg ^{–1})	
Sands (light colored)	3–5	~1
Sands (dark colored)	10–20	1–3
Loams	10–15	1.5–5
Silt loams	15–25	2–6
Clay and clay loams	20–50	3–5
Organic soils	50–100	20–40

(NH_4^+) > Na^+ . Cations with greater charge are more strongly adsorbed. For cations of similar charge, adsorption strength is determined by the size of the hydrated cation; greater hydrated cation radii (Mg^{2+}) reduce adsorption because they cannot get as close to the exchange surface as smaller cations (Ca^{2+}).

Base saturation (BS) represents the percentage of CEC occupied by bases [Ca^{2+} , Mg^{2+} , K^+ , and (Na^+)], which increases with increasing soil pH (Fig. 4). The availability of Ca^{2+} , Mg^{2+} , and K^+ increases with increasing %BS. For example, 80% BS provides essential nutrients (cations) to plants easier than 40% BS. At pH 5 and 6, most soils have ~50% and 80% BS, respectively.

Soil solution anions are adsorbed into (+) charged sites on the surface of clay minerals and soil OM. AEC increases with decreasing soil pH (Fig. 3). The adsorption strength is dihydrogen phosphate ion ($H_2PO_4^-$) > sulfate ions (SO_4^{2-}) >> nitrate ion (NO_3^-) = chloride ion (Cl^-). In most soils, $H_2PO_4^-$ is the primary anion adsorbed although in severely acid soils SO_4^{2-} adsorption represents a major source of plant-available S.

Soil acidity and alkalinity. Acid soils usually occur in regions where annual precipitation is >600–800 mm. Natural soil acidification is enhanced with increasing rainfall since rain $pH \leq 5.7$, depending on pollutants such as sulfur

Fig. 3 Permanent and pH-dependent charge associated with clay minerals. As soil pH increases (+), charge decreases and (–) charge increases, increasing CEC.

Fig. 4 Influence of soil pH on BS% in mineral soils.

dioxide, nitrogen dioxide, and others which lower rainfall pH. Management factors increasing soil acidity include the following: 1) use of acid forming fertilizers; 2) crop removal and/or leaching of cations decreasing %BS; and 3) the decomposition of organic residues. Optimum soil pH depends on the crop and ranges between 4.5 and 7.5. Neutralizing soil acidity by liming to $\text{pH} \geq 5.5$ will reduce exchangeable Al^{3+} to ~20% of the CEC and will usually prevent Al toxicity-related yield loss.

Calcareous soils contain the solid mineral calcium carbonate (CaCO_3), exhibit soil $\text{pH} \geq 7.2$, and occur in regions of <500 mm annual precipitation. In areas where annual rainfall is >800 mm, the acidifying effect of rain increases depth to CaCO_3 to below the root zone. If CaCO_3 exists, all of it must be dissolved and neutralized before soil pH could decrease. In most situations, reducing soil pH by neutralizing CaCO_3 is too costly. High soil pH in calcareous soils reduces the availability of several micronutrients [e.g., ferric ions and zinc ions (Zn^{2+})].

Excessive salts in alkaline soils can reduce plant growth and yield depending on crop sensitivity. In arid and semiarid regions as H_2O evaporates, salts are deposited near the soil surface to form saline and/or sodic soils and are characterized by their electrical conductivity (EC_{se}), soil pH, and exchangeable Na% (ESP; Table 3). In saline soils, soluble salts interfere with plant growth, although salt tolerance varies with plant species. In sodic soils ($\text{ESP} > 15\%$), soil aggregates disperse reducing infiltration and soil H_2O permeability, while excess Na can also create nutritional disorders. Saline-sodic soils exhibit both high salt and Na content.

Soil OM

Soil OM represents organic materials in various stages of decay (Fig. 5). The most important fraction to soil fertility is the stable OM that is relatively resistant to further decomposition (Fig. 5). Soil humus, the largest component of soil OM, is relatively resistant to microbial degradation but is essential for maintaining optimum soil physical conditions (aggregation, infiltration, aeration, etc.) important for plant growth. Fresh plant and animal residues undergo rapid decomposition. The microbial biomass represents soil microorganisms responsible for mineralization and

Fig. 5 Pathway of the degradation of plant and animal residues to stable soil OM. The mineralization of organic compounds produces plant-available nutrients.

immobilization processes that influence the availability of N, phosphorus (P), S, and other nutrients. Residue decomposition and stable OM formation depend on climate, soil type, and soil and crop management practices. Soil OM greatly influences various soil processes and properties that influence nutrient availability (Table 4). For example, increasing soil OM increases soil aggregation and decreases bulk density, which improves H_2O infiltration, air exchange, root proliferation, and crop productivity. Soil OM levels depend on soil and crop management. If management is changed, a new OM level is eventually attained that may be lower or higher than the previous level. Management systems should be adopted that sustain or increase soil OM and productivity. Proper nutrient management will produce high yields, which will increase the quantity of residue and soil OM.

Mineral solubility in soils

Mineral solubility refers to the concentration of ions in solution supported or maintained by solid phase mineral(s). There are many soil minerals influencing nutrient concentrations in soil solution. For example, in acid soils, $\text{FePO}_4 \cdot 2\text{H}_2\text{O}$ influences P availability by the following reaction:

The K_{sp} for this reaction is as follows:

$$K_{\text{sp}} = (\text{H}_2\text{PO}_4^-)(\text{H}^+)$$

As H_2PO_4^- decreases with P uptake, strengite dissolves to resupply or maintain solution H_2PO_4^- concentration. This reaction also shows that as H^+ increases (decreasing pH), H_2PO_4^- decreases. Therefore, specific P minerals present in soil and the concentration of solution P supported by these

Table 3 Classification and properties of salt-affected soils.

Classification	EC_{se} (dS m^{-1}) ^a	Soil pH	ESP% ^b	Physical condition
Saline	>4	<8.5	<15	Normal
Sodic	<4	>8.5	>15	Poor
Saline-sodic	>4	<8.5	>15	Normal

^a EC_{se} represents electrical conductivity of soil H_2O removed from a sample of saturated soil. Increasing salt concentration increases EC_{se} .

^bESP% (exchangeable Na percent) represents the percentage of CEC occupied with Na^+ .

Table 4 Characteristics of soil OM and associated effects on soil and plants.

Property	Effect on soil	Effect on plant
Soil color	Imparts dark color	Darker color causes soils to warm faster; >surface soil temperature advances germination and seedling growth (depending on residue cover)
H ₂ O holding capacity	Holds ~20 times weight in H ₂ O	>H ₂ O holding capacity, >plant-available H ₂ O especially in sandy soils
OM–clay interaction	Cements soil particles into aggregates	Improve soil structure and porosity and enhances gas exchange, infiltration, root proliferation in soil
Ion exchange/buffering	Increases CEC and AEC 20–70%	>Nutrient retention and availability
Mineralization/immobilization	Nutrient cycling	Increases nutrient availability and retains/conserves nutrients
Chelation	OM forms stable metal (M ⁿ⁺) complexes	Enhance micronutrient availability
Solubility	Insoluble humus–clay complexes, many soluble low MW organic compounds	OM-bound nutrients less likely to leach

MW: molecular weight.

minerals are dependent on solution pH. Solubility relationships are particularly important for plant availability of P and many of the micronutrients.

Buffer capacity

As nutrient concentration in the soil solution decreases by plant uptake, nutrients in soil solution are replenished from exchange surfaces, soil OM, or the dissolution of soil minerals (Fig. 2). Nutrient supply to plants depends on nutrient concentration in solution and on *buffering capacity* (BC) or the ability of the soil to resupply nutrients to solution (Fig. 6). For example, as plant roots absorb K⁺, adsorbed K⁺ on the CEC is desorbed to resupply solution K⁺. Similarly, H₂PO₄[−] adsorbed into the AEC will desorb, while P-bearing minerals may also dissolve to supply solution H₂PO₄[−] (Fig. 2). Both processes, desorption from exchange sites and the dissolution of minerals, comprise soil BC.

Nutrient Transport from Soil to Roots

Nutrient absorption by plant roots requires contact between the nutrient ion and the root surface (Fig. 2). Nutrients

Fig. 6 Influence of soil texture on the quantity of adsorbed and solution nutrient concentrations. Buffer capacity is the ratio of adsorbed to solution nutrient concentration. To maintain the same solution concentration in both soils, the clay soil should have a greater adsorbed nutrient concentration than the sand soil. As solution concentration decreases with the nutrient uptake, the clay soil will have a greater supply of adsorbed nutrients to resupply the soil solution.

reach the root surface by *root interception*, *mass flow*, and *diffusion*. Although each is important, mass flow and diffusion dominate nutrient transport (Table 5).

Root interception represents ion exchange through physical contact between the root and exchange surfaces. Ions

Table 5 Significance of root interception, mass flow, and diffusion in nutrient transport to roots. For some nutrients, the quantity transported can exceed that required by the crop.

Nutrient	Nutrients required (kg ha ^{−1}) for 10 ton ha ^{−1} of corn	Percentage supplied by		
		Root interception	Mass flow	Diffusion
N	200	1	99	0
P	40	2	4	94
K	180	2	20	78
Ca	45	120	440	0
Mg	50	27	280	0
S	22	4	94	2
Cu	0.11	8	400	0
Zn	0.36	25	30	45
B	0.22	8	350	0
Fe	2.2	8	40	52
Mn	9.3	25	130	0
Mo	0.01	8	200	0

Notes: The contribution of diffusion was estimated by the difference between total nutrient needs and amounts supplied by interception and mass flow. If interception + mass flow is >100%, then diffusion = 0.

such as H^+ adsorbed into root surfaces may exchange with ions adsorbed into mineral and OM surfaces through direct contact of both surfaces. As roots and associated mycorrhiza develop, more ions adsorbed into soil surfaces are contacted by increasing root mass. The quantity of nutrients in direct contact with plant roots is the amount in a soil volume equal to the root volume (~2% of soil volume).

Mass flow occurs when ions in soil solution are transported to the root by the transpiration of H_2O by the plant, H_2O evaporation at the soil surface, and percolation of H_2O in the soil profile. The quantity of nutrients transported by mass flow is determined by the rate of H_2O flow and the nutrient concentration in the soil H_2O . Decreasing soil moisture decreases H_2O transport to the root surface.

Diffusion occurs when an ion moves from an area of high to low concentration. As roots absorb nutrients from the soil solution, concentration at the root surface is lower than that in solution not influenced by the root. Therefore, increasing nutrient concentration gradient increases diffusion rate toward the root. A high plant requirement for a nutrient results in a large concentration gradient, favoring a high diffusion rate. Most of the P and K move to the root by diffusion (Table 5).

The importance of diffusion and mass flow in supplying ions to the root surface depends on the ability of the solid phase of the soil to replenish or buffer the soil solution. Ion concentrations are influenced by the types of clay minerals and OM in the soil and the distribution of cations and anions on CEC or AEC.

Mass flow and diffusion processes are also important in nutrient management. Soils that exhibit low diffusion rates because of high BC, low soil moisture, or high clay content may require the application of immobile nutrients near the roots to maximize nutrient availability and plant uptake.

Nutrient Mobility in Soil

Nutrient mobility in soil influences ion transport to plant roots, the evaluation of nutrient availability to plants, and ultimately nutrient management decisions. Nutrient mobility varies between ions, where NO_3^- , SO_4^{2-} , Cl^- , and $H_3BO_3^0$ are not strongly attracted to exchange sites and are soluble in soils, so they can readily move through the root zone with H_2O . As a result, mobile nutrients within the whole soil volume occupied by the plant root system are available for transport to the root in percolating and transpirational H_2O (Fig. 7). The relative mobility of each nutrient will depend on soil pH, temperature, moisture, soil texture, type of clay, and OM content.

Immobile nutrients interact with mineral and OM surfaces, are less soluble, and do not readily move throughout the root zone (Fig. 7). While classified as immobile nutrients in soil, some are more mobile than others. Generally, NH_4^+ , K^+ , Ca^{2+} , and Mg^{+2} are more soluble and mobile than the micronutrient cations and much more mobile than $H_2PO_4^-/HPO_4^{2-}$ and MoO_4^{2-} . As these nutrients are relatively immobile in soil, plant roots access them from a small soil volume surrounding individual roots. Plants create a small zone around the root that has the very low concentration of these immobile nutrients due to plant uptake, causing a concentration gradient encouraging nutrient diffusion. If the soil has a high buffer capacity for an immobile nutrient, then the solution can be replenished and diffusion continues. With a low buffer capacity, solution concentration (and diffusion) ultimately decreases, causing a nutrient deficiency.

Understanding nutrient mobility in soils is essential to managing nutrient applications to maximize plant growth and recovery of applied nutrients by the plant. For example,

Fig. 7 Relationship between nutrient mobility and nutrient extraction zones. Plants obtain mobile nutrients from the whole soil volume occupied by plants roots. In contrast, plants obtain immobile nutrients from the small soil volume immediately surrounding the plant root.

mobile nutrients can be broadcast or band applied with fairly similar results because of their mobility in soil. However, P is generally placed in concentrated bands because it is generally immobile in soil.

NUTRIENT MANAGEMENT

Efficient nutrient management programs supply plant nutrients in adequate quantities to sustain maximum plant growth and yield while minimizing environmental impacts of nutrient use. Substantial economic and environmental consequences occur when nutrients limit plant productivity or when nutrients are applied in excess of plant requirement.

The essential requirements of an effective nutrient management plan are as follows: 1) assessment of crop nutrient requirement; 2) evaluation of nutrient supplying capacity of soil; 3) quantify optimum nutrient rate; 4) identify appropriate and available nutrient source(s); 5) determine most efficient nutrient placement method; and (6) schedule nutrient applications to meet plant nutrient demand. Management decisions will vary depending on the specific nutrient and crop.

Assessing Plant Nutrient Requirement

The quantity of nutrients required by plants depends on the nutrient (Table 1), plant characteristics (specific crop, yield level, variety, or hybrid), growing season environmental factors (moisture, temperature, etc.), soil characteristics (soil properties, soil fertility, and landscape position), and soil and crop management. Management practices that enhance crop productivity will increase nutrient requirements.

Evaluation of Nutrient Supplying Capacity of the Soil

The *soil testing–nutrient recommendation system* is comprised of the following four consecutive steps: 1) collect a representative soil sample from the field; 2) determine the quantity of plant-available nutrient in the soil sample (soil test); 3) interpret the soil test results (Fig. 8); and 4) estimate the quantity of nutrient required by the crop. The greatest potential for error is in collecting a soil sample that accurately represents the field sampling area. Great care is required in identifying the sampling area from which a composited sample is sent to a laboratory for analysis. Selected parameters used in separating sampling areas within a field include differences in topography, soil type, crop productivity, and past management.

Soil testing is essential for determining the relative availability of plant nutrients in soil. Soil tests extract part of the total nutrient content in soil that is related to (but not

Fig. 8 As soil test levels increase, the capacity of the soil to provide sufficient plant nutrients increases, reducing the quantity of nutrients added to meet crop requirement.

equal to) the quantity of nutrients removed by plants. Thus, the soil test level represents an *index* of nutrient availability representing the relative nutrient sufficiency of a soil (Fig. 8).

Quantify Optimum Nutrient Rate

Soil test interpretation for the purposes of making nutrient recommendations is influenced by the mobility of the nutrient (Fig. 7). With mobile nutrients, crop yield is proportional to total quantity of nutrient present in the root zone because of minimal interaction with soil constituents (Fig. 2). For NO_3^- , SO_4^{2-} , and Cl^- , a 0.5–1.0 m profile sample is important for accurately assessing mobile nutrient availability (Fig. 7). For N, recommendations are usually based on yield goal, where N required to produce each unit of yield is known (e.g., $0.3 \text{ kg N} \cdot \text{kg}^{-1} \text{ grain}$). This concept is also evident when additional in-season N is recommended because better-than-average growing conditions increased the yield potential above initial estimates provided before planting. Additional factors affecting optimum N rate include the estimates of N mineralized during the growing season from previous legume crops and organic N amendments (manures, biosolids, etc.). With immobile nutrients (e.g., H_2PO_4^- , K^+ , and Zn^{2+}), crop yield potential is limited by the quantity of nutrient available at the soil–root interface. Generally, the solution concentrations of immobile nutrients are low, and replenishment occurs through exchange, mineralization, and mineral solubility reactions (Fig. 2). If nutrient uptake demand exceeds the soil’s capacity to replenish solution nutrients, then plant growth and yield will be limited. Immobile nutrient recommendations are based on sufficiency levels determined through soil testing (Fig. 8). Soil tests for immobile nutrients provide an index of nutrient availability that is generally independent of environment.

Identify Nutrient Source(s)

The primary criteria for selecting a nutrient source are availability and cost. For example, if organic nutrient sources (manures, biosolids, etc.) are available, they should be utilized if the cost per unit of plant-available nutrients is comparable to inorganic fertilizers. There are important benefits of using organic sources beyond their nutrient value, which should also be considered (Table 4). Nutrient content of organic materials must be quantified to determine the application rate needed to meet crop nutrient requirement in the year of application.

In most cases, there are few differences in crop response between inorganic fertilizer sources. Although most plants prefer a mixture of NH_4^+ and NO_3^- , most NH_4^+ or NH_4^+ -forming N sources (urea-based products) readily dissolve and nitrify to form NO_3^- . Under the conditions of high denitrification, volatilization, and/or nitrification potential, numerous additives or coatings (solid fertilizers) are available to reduce losses of applied NH_4^+ and NO_3^- . When applying nutrients with the seed, nutrient sources with a low salt index are important in reducing salt damage to germinating seeds and seedlings.

Nutrient Placement Methods

Nutrient placement decisions involve knowledge of crop and soil characteristics, whose interactions determine nutrient availability. Although numerous placement methods have been developed, the primary goal is to ensure optimum nutrient availability from plant emergence to maturity. Vigorous seedling growth (i.e., no early growth stress) is essential to optimize plant growth and yield. Merely applying nutrients does not ensure that they will be absorbed by the plant.

Fertilizer placement options generally involve surface or subsurface applications before, at, or after planting. Placement practices depend on the crop and crop rotation, degree of deficiency or soil test level, nutrient mobility in the soil,

degree of acceptable soil disturbance, and equipment availability.

Preplant application

Preplant applications are important to provide adequate nutrient supply during germination and early plant growth stages. Broadcast nutrients are applied uniformly on the soil surface over the entire area before planting and can be incorporated by tillage (Fig. 9). In no-till, there is limited opportunity for incorporation; thus, broadcast N applications may reduce N recovery by the crop due to enhanced immobilization, denitrification, and volatilization of applied N. Crop recovery of nutrients can be increased by placement below the soil surface where soil moisture might be more favorable for nutrient uptake (Fig. 9). Surface band applied fertilizers can be effective before planting (Fig. 9); however, if not incorporated, dry surface soil conditions can reduce nutrient uptake, especially with immobile nutrients. Surface band N applications can improve N availability compared with broadcast application in some soils and cropping systems due to reduced interaction with surface plant residues.

Animal waste and other organic nutrient sources are commonly preplant applied, usually as a broadcast or subsurface band placement. Broadcast applications, especially unincorporated, are subject to greater denitrification and volatilization N losses and surface runoff losses of all nutrients.

At planting application

Fertilizer placement can occur at numerous locations near the seed (2–8 cm below and/or to side of seed), depending on equipment and crop (Fig. 9). Fertilizer application with the seed is a subsurface band used to enhance early seedling vigor, especially in cold, wet soils. Usually, low nutrient rates are applied to avoid germination or seedling damage.

Fig. 9 Options for the application of nutrients at or below the soil surface.

Fertilizers can be surface applied at planting in bands directly over or to the side of the row (Fig. 9).

After planting application

Broadcast application after planting is commonly referred to as topdressing. Topdress N applications are common on permanent or close seeded crops (turf, small grains, pastures, etc.); however, N immobilization with high surface residue reduces the recovery of topdress N. Topdressed P and K are not as effective as preplant applications. Side-dress N application is common in row crops (corn, grain sorghum, etc.) as either a surface or subsurface band. Side-dress applications increase flexibility; since applications can be made almost anytime, equipment is operated without damage to the crop. Side-dress placement is particularly suited for spatially variable N application using remote sensors mounted on the applicator to guide application rate. Subsurface side-dress applications too close to the plant can cause damage by either root pruning or nutrient toxicity. The side-dress application of immobile nutrients (e.g., P and K) is not recommended because most crops need P and K early in the season.

Timing of Nutrient Applications

Nutrients are needed in the greatest quantities during the periods of maximum plant growth. Thus, nutrient management plans are designed to ensure adequate nutrient supply before the exponential growth period. In this case, N should be applied preplant or split applied before the stem extension phase. All of the immobile nutrients, including P and K, should be applied before planting. Knowledge of crop-uptake patterns facilitates improved management for maximum productivity and recovery of applied nutrients.

Variable Nutrient Management

Variable or *site-specific* nutrient management can improve nutrient use efficiency by distributing nutrients based on spatial variation in yield potential, soil test levels, and other spatially variable factors that influence soil nutrient

availability and crop nutrient demand. Preseason and in-season assessments of spatial information are two variable nutrient management approaches used to guide nutrient application decisions.

CONCLUSION

Meeting food needs for a growing population requires increased food production on the same or less agricultural land area. Land managers must adopt economically viable technologies that maintain, enhance, or protect the productive capacity of our soil resources to ensure future food and fiber supplies. While organic nutrient sources are important to meeting the nutritional needs of higher-yielding cropping systems, inorganic fertilizer nutrients will remain the predominant nutrient source. The challenge to the agricultural community is to ensure maximum recovery of applied nutrients, regardless of source, through use of diverse soil, crop, H₂O, nutrient, and other input management technologies to maximize plant productivity. Accomplishing this will significantly reduce nutrient losses to the environment.

Nutrients: Deficiency and Toxicity Symptoms

Noel J. Grundon

Land and Water, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Atherton, Queensland, Australia

Abstract

When plants suffer from too much (a toxicity) or too little (a deficiency) of the mineral elements that are their food, they develop visual symptoms on their leaves, stems, fruits, and roots that are characteristics for the deficiency or toxicity. If we can understand these visual symptoms, we are better able to diagnose the causes of the disorders and to commence correcting the problem. In order to understand this visual language of sick plants, it is advantageous to understand the processes that underlie symptom development.

SYMPTOM DEVELOPMENT

Because mineral nutrients are associated with specific metabolic process, the development of symptoms and their location on the plant can be considered in relation to the function and mobility of the mineral elements within the plant.

In Relation to the Functions of Elements

The functions of mineral elements have been covered widely in the literature (see Marschner)^[1] and include the following:

1. Being an integral constituent of an essential metabolite, complex, or macromolecular assembly, e.g., amino acids; proteins (nitrogen and sulfur); enzymes and coenzymes (nitrogen, sulfur, iron, copper, zinc, manganese, nickel, and molybdenum); nucleic acids (DNA and RNA), adenosine diphosphate, and adenosine triphosphate (nitrogen and phosphorus); cell walls (calcium); and chlorophyll (nitrogen and magnesium).
2. Being an activator of an enzyme or regulator of an enzyme-mediated process, e.g., potassium, calcium, magnesium, zinc, manganese, and nickel.
3. Playing a nonstructural role in a physiological process, e.g., protein metabolism; pollen tube growth (boron); auxin metabolism (boron and zinc); membrane integrity and function (phosphorus, calcium, boron, and zinc); photosynthesis (potassium, magnesium, chlorine, and manganese); carbohydrate metabolism and partitioning (potassium, sulfur, magnesium, copper, and zinc); stomatal movement (potassium and chlorine); and messenger in environmental signals (calcium).

Mineral elements may have nonspecific roles in addition to specific roles. For example, the ions of many elements play a role in cation–anion and pH balance, osmoregulation, and maintaining electrical neutrality within cells. Another

example is the quality of harvested products: Calcium deficiency can lead to decreased quality of fruit causing bitter pit in apple, blossom-end rot in tomato, and jelly-fruit in mango.

If an element is involved in the uptake or metabolism of another element, the symptoms may not be clearly defined, and it can be difficult to identify the causal element. For example, nitrogen and sulfur are biochemically related in the formation of proteins. In forest trees, there is no inorganic nitrogen in the foliage, and the close biochemical linkage between organic nitrogen and organic (and total) sulfur causes the rate of nitrogen uptake to be limited by the rate of sulfur accumulation.^[2] Therefore, in many forest and horticultural tree species, the symptoms of mild nitrogen and sulfur deficiency are very similar.^[3]

In Relation to the Mobility of the Elements

Mineral elements differ markedly in their mobility and extent and retranslocation. All mineral elements are highly mobile within the xylem, but their mobility within the phloem can be divided into the following three classes: 1) readily mobile; 2) variably mobile; and 3) poorly mobile. Mineral elements that are readily mobile in the phloem (e.g., nitrogen, potassium, phosphorus, and magnesium) are easily retranslocated from older to younger tissues when nutrient supply becomes limiting. Deficiency symptoms of these elements develop first in the older tissues and advance toward the younger tissues as the deficiency becomes more severe. Nutrients that have low phloem mobility (e.g., calcium, boron, and iron) develop symptoms first in immature tissues. However, elements that are readily mobile under one set of conditions may appear to be only partly mobile or even immobile under different conditions. For example, magnesium is normally classed as a mobile element, and deficiency symptoms appear first on older leaves when a constant but inadequate supply occurs. However, when magnesium supply to the roots of subterranean

clover was interrupted suddenly, symptoms developed first on the younger leaves.^[4]

Some elements show variable mobility depending on the degree of deficiency and either the nitrogen or phosphorus status of the plant. For example, copper, zinc, and molybdenum are relatively immobile when nitrogen supply is adequate, and there is little or no movement of these elements from old leaves of plants deficient in them. Here, symptoms occur mainly in young tissues. However, should nitrogen become limited, copper, zinc, and molybdenum can be remobilized from older to younger leaves along with the retranslocation of nitrogen,^[5] and the symptoms of nitrogen deficiency are likely to dominate.

If a toxic nutrient element interacts with the metabolism of another element, symptoms of the toxicity occur on older tissues, while symptoms of deficiency of the other element occur on those tissues characteristic for that nutrient. For example, on acidic soils, excessive levels of soluble manganese can induce iron deficiency in some plants, thereby causing the development of manganese toxicity symptoms on older leaves and iron deficiency symptoms on younger leaves.^[6]

DIAGNOSTIC SYMPTOMS

Descriptions and color photographs of mineral nutrient deficiencies and toxicities in a range of species have been published (see Grundon et al.^[7] for a comprehensive list). Symptom expression can vary greatly from one species to another and also among cultivars within species. It is most important to check the specific symptoms described for a particular species. However, the first requirement in the use of visual symptoms is knowledge of the appearance of a healthy plant of the species concerned. Knowledge of the symptoms caused by insect pests and diseases also aids in the final diagnosis.

Deficiency

Because one element may have many functions, the characteristic symptoms of a deficiency are those associated with the function that is most sensitive or dominates. For example, zinc is associated with auxin metabolism, nucleotide synthesis, and membrane integrity, but it is an impairment of auxin metabolism in zinc-deficient plants that leads to the characteristic symptoms of leaf distortion and failure of the internodes to elongate. General symptoms of deficiency of some nutrient elements are listed in Table 1.

Toxicity

Symptoms of nutrient toxicity occur more commonly in those tissues that have had a longer period of time to accumulate ions, e.g., the margins of older leaves in dicotyledons or the leaf tips in monocotyledons and gymnosperms.

Table 1 General symptoms of mineral element deficiency (note that symptoms for specific crops and cultivars may differ).

Element	General symptoms
Nitrogen	Pale yellow chlorosis of the older leaves spreading to younger leaves, often with reddening in cold weather
Phosphorus	Dark green foliage; reddening or purpling of older leaves spreading to younger leaves
Potassium	Near-marginal to marginal chlorosis and necrosis of older leaves
Calcium	Death of the terminal meristems; distorted growth or death of leaf tips; disorders of fruit (e.g., blossom-end rot of tomato; bitter pit in apple; jelly-fruit in mango)
Magnesium	Marginal or interveinal chlorosis and necrosis of older leaves
Sulfur	Pale yellow chlorosis of immature leaves
Iron	Interveinal chlorosis or bleaching of immature leaves
Copper	Distorted growth of immature leaves or death of leaf tips; failure of fertilization and fruit set
Zinc	Little leaf, rosetting, and shortening of the internodes
Manganese	Interveinal chlorosis, necrotic spots, or streaks on older or middle leaves
Boron	Death of growing points; failure of fertilization and fruit set
Nickel	Interveinal chlorosis (monocotyledons) or leaf tip necrosis (dicotyledons)
Molybdenum	General chlorosis (legumes); mottled pale appearance (nonlegumes)

Source: From Dell, Malajczuk, et al.,^[3] Grundon, Edwards, et al.,^[6] Blamey, Edwards, et al.,^[8] and Grundon.^[9]

Thus, marginal chlorosis and necrosis in older leaves are common symptoms of many nutrient toxicities.^[6,8,9] General symptoms of toxicity of some mineral elements are listed in Table 2.

Advantages, Disadvantages, and Limitations

The use of visual symptoms to diagnose nutrient disorders has distinct advantages, including: 1) the technique can be applied in the field; and 2) it is not dependent on costly laboratory support services. However, even in the hands of experienced practitioners, there are a number of major disadvantages in relying on visual symptoms as the sole diagnostic tool, including the following:

1. When the disorder is mild or transient in nature, no foliar symptoms may be produced, and clearly defined symptoms may occur only when the disorder is severe enough to depress yield.

Table 2 General symptoms of mineral element toxicity (note that symptoms for specific crops and cultivars may differ).

Nutrient	Visual symptoms
Nitrate-nitrogen	Marginal scorch of leaves followed by interveinal collapse
Ammonium-nitrogen	Necrosis and blackening of margins of leaves or leaf tips
Phosphorus	Marginal scorch and interveinal necrosis and death of older leaves
Sodium	Marginal scorch and necrosis of older leaves
Sulfate	Marginal scorch and necrosis of older leaves
Chloride	Bronzed chlorosis and marginal scorch of older leaves
Manganese	Marginal chlorosis and brown necrotic peppering on older leaves
Aluminum	Roots stunted, brown, and multibranched; symptoms on shoots may resemble phosphorus deficiency
Zinc	Interveinal necrosis on older leaves
Boron	Interveinal chlorosis becoming marginal necrosis on older leaves
Nickel	Transverse light and dark bands on immature leaves

Source: From Dell, Malajczuk, et al.,^[3] Grundon, Edwards, et al.,^[6] Blamey, Edwards, et al.,^[8] and Grundon.^[9]

- For some micronutrient disorders, environmental factors (e.g., light and zinc deficiency symptoms) have a profound effect on the appearance or severity of the symptoms.
- Under certain conditions, different nutrient disorders can produce similar symptoms.
- By the time definitive symptoms become evident, it is often too late to correct the problem in that growing season.

The Final Diagnosis

Despite the limitations to its application, the use of visual symptoms are a valuable diagnostic tool. It is important to recognize that the use of visual symptoms provides a preliminary diagnosis only. Confirmation by other methods such as plant and soil analyses, pot culture assays, field experiments, or test strips is an essential second step.

Nutrients: Diffusion, Bioavailability, and Plant Uptake

Niels Erik Nielsen

Plant Nutrition and Soil Fertility Lab, Department of Agricultural Sciences, Royal Veterinary and Agricultural University, Frederiksberg, Denmark

Abstract

Entry of nutrient elements into plants and, therefore, into the food web of human beings depends on the capability of the soil to release and maintain a concentration higher than the minimum concentration ($c_{\min}$) of elements in the soil solution at the root surface, and on the uptake capacity of the plant roots. Root-induced rhizosphere processes influence nutrient availability, maintenance of the nutrient concentration in the soil solution and plant uptake. The entry into plants and the associated flux of a nutrient element toward root surface may be controlled by a number of rate-limiting and/or rate-determining processes. One of the rate-limiting processes may be the flux by diffusion from the solid constituents in the soil via the soil solution to the nutrient-absorbing cell membrane in root tissue near the root surface. The goal of good agronomy is always to obtain a useful and sustainable modification of rate-limiting and/or rate-determining processes in the soil—plant atmosphere system, aiming at high yields and qualities of the crops. This goal requires identification of the rate limiting and/or rate-determining steps, an understanding of their dynamics, and knowledge of how to obtain appropriate modifications of these steps.

SOIL PLANT SYSTEM

The movement of any nutrient element, M , from solid soil constituents to the root surface, and its entry into plants, can be divided into a sequence of processes (steps), as shown in Fig. 1, which also indicates major agronomical actions used to improve nutrition and growth of crop plants. The $\leftrightarrow$ denotes solid-phase processes slowly approaching equilibrium, or microbial-mediated net mineralization of nitrogen, sulfur, and phosphorus, for example. Also denoted are the source/sink processes by which diffusible nutrients are being produced or removed by chemical, physical, and biological transformation processes. In Fig. 1, L denotes ligands that are any dissolved solute reacting with M to form ML , which are organic complexes and ion pairs dissolved in the soil solution. The occurrence of L and, therefore, of ML , increases the total concentration ($M + ML$) and mobility of the nutrient element. The $\rightleftharpoons$ denotes reversible processes, which are spontaneously approaching equilibrium. Depending on ion species, ion concentration at the root surface, and plant age, the symbol $\rightleftharpoons$ denotes processes that may be irreversible. The irreversible processes are always rate limiting and/or rate determining, whereas reversible processes may be rate limiting, only. Processes 2 and 3 are in the vicinity of the soil particle, whereas process 7 is in the vicinity of the root. Processes 4, 5, and 6 are transport processes by mass flow and diffusion due to water uptake and nutrient uptake (process 8) by cell membranes of root cells near the root surface or root hairs. Process 9 is the nutrient translocation in the plant. Process 10 is the plant growth that also integrates the absorbed nutrient into the plant tissue. Processes 8, 9,

and/or 10 create the concentration (electro-chemical) gradients for irreversible net flux of nutrients from the soil–soil solution system into the plants. Hence, at any time, the rate-determining processes (Fig. 1) are then either the release of the nutrient into the pool of plant available nutrient (source/sink processes in the soil) or the nutrient uptake into the roots, its translocation/circulation in the plant, and/or the rate by which the nutrient is built into new tissue. Mass flow and diffusion may be rate limiting only, and not rate determining. Usually only a small fraction of the plant-available nutrients is dissolved in the soil solution. This implies that the bioavailability of nutrients to plant roots is governed by several soil properties including, e.g., the characteristics of process 2 in Fig. 1 and the possibilities for movement via soil solution to the root surface by mass flow and diffusion. The concept of a *bioavailable nutrient* can then be defined as a nutrient element that is present in a pool of diffusible (available) nutrients that are close enough to arrive at water- and/or nutrient-absorbing root surfaces during a period of 10 days, for example. This seems to fit with the observation that most of the depletion zones of slowly moving nutrients, such as phosphorus, are created during the first 10 days after root growth into a new soil volume unit.^[1] The bioavailable quantity of a nutrient in the soil is affected by at least five different groups of processes as indicated in Table 1.

DIFFUSION

Diffusion is the net movement of a solute or a gas from a region that has a higher concentration, to an adjacent region

Fig. 1 Flux of a nutrient element in the soil plant atmosphere system and agronomy actions; nutrient element (M), ligands (L), reversible $\rightleftharpoons$ and irreversible processes.

Source: From Nielsen.^[2]

that has a lower concentration. Diffusion is a result of the random thermal motions of molecules in the considered solids, solution, or air. The net movement caused by diffusion is a statistical phenomenon because the probability of

the molecules' movement from the concentrated to the diluted region is greater than vice versa. Fick (1855) was one of the first to examine diffusion on a quantitative basis. The basic equation Eq. 1 to express diffusion, e.g., to a root is known as Fick's first law of diffusion:

$$F = -D \frac{\partial C}{\partial r} \quad (1)$$

in which F is the diffusive flux ($\text{mol cm}^{-2}\text{s}^{-1}$) of a nutrient in the r -direction normal to the root cylinder. The driving force (the gradient in the electro-chemical potential) is, in most cases, approximated by the concentration gradient

$$\frac{\partial C}{\partial r} \text{ (mol cm}^{-4}\text{)}$$

and D is the diffusion coefficient (cm^2s^{-1}). They way to describe diffusion processes mathematically under various conditions has been presented by Jost^[3] and Crank.^[4] Great contributions to our understanding of solute movement in the soil root system by mass flow and diffusion have been given or reviewed by Nye and Tinker^[5,6] and Barber.^[7] Willigen and colleagues^[8] reviewed some aspects of the modeling of nutrient and water uptake by plant roots.

Nutrient Movement by Mass Flow and Diffusion from Soil to Plant Roots

Nutrients bound to the solid-soil phase are virtually immobile in the sense of its movements to roots. The nutrient has to be released into the soil solution as shown in Fig. 1. Furthermore, contact between the root

Table 1 Processes and factors involved in nutrient transfer from soil to plant roots.

Process	Factors
Release, mineralization, and dissolvment of the nutrient in the soil solution	Chemical and physical properties of the solid phases, temperature, soil water content, and activity of the microbial biomass
Root development	Root length, distribution of roots in the root zone, root morphology, root hairs, rate of root growth, and root surface contact area with soil solution
Solute movement by mass flow and diffusion to roots	Transpiration rate (w_o), concentration of the nutrient in the soil solution (c_b), effective diffusion coefficient (D_e), nutrient buffer power of the soil (b)
Rhizosphere processes, increasing the rate of nutrient release in the soil	Depletion of the soil solution for nutrients by the roots; root exudates as protons, reducing agents, chelates, organic anions, enzymes; modification of microbial activity; mycorrhizal and Rhizobium symbioses
Nutrient uptake	Concentration of the nutrient at the root surface (c_o); transport kinetic parameters of nutrient uptake by the roots ($\bar{I}_{\max}$, K_m , and $c_{\min}$)

Source: From Nielsen.^[2]

and nutrient-absorbing membranes in the root tissue near the root surface and the soil solution is a prerequisite for nutrient uptake. Contact to nutrient pools can be brought about by two means as follows: 1) growth of roots to the sites where nutrient pool are located (root interception) and 2) movement of the nutrient from the bulk (the pool) of the soil to the root surface. Even so, nutrients may at any time move over a certain distance in the soil solution and cell wall before they reach the outside cell membrane of a root hair or a root cortical cell for uptake. The mechanisms for these transports are mass flow and diffusion.^[5,9] The driving force for the net movement of nutrients (Fig. 1) is the water and the selective nutrient uptake by the plant root, creating a concentration gradient (dc/dr). The general equation of continuity (mass balance) used to describe movements in a direction normal to a root cylinder at radial distance r and time t may partly be developed from Eq. 1, extended and expressed as

$$\left[b \frac{\partial c}{\partial t} \right]_r = - \left[\frac{1}{r} \frac{\partial r F_T}{\partial r} \right]_t + U_{r,t} \quad (2)$$

in which

1. U is the production/consumption term (mole $\text{cm}^{-3} \text{s}^{-1}$) at r (radial distance from the center of the root) and t (time).
2. b is the buffer power (dC/dc) in which C is the total concentration of diffusible solute in the soil and c is the concentration of solute in the soil solution.
3. F_T is total net flux of solute by mass flow and diffusion (mole $\text{cm}^{-2} \text{s}^{-1}$).

$$F_T = F_m + F_d$$

where $F_m = wc$ in which w is the flux of soil solution in the direction of the root ($\text{cm}^3 \text{cm}^{-2} \text{s}^{-1}$) and c is the nutrient concentration of soil solution (mole cm^{-3}). The expected rates of water flux at the root surface are $0.2\text{--}1 \cdot 10^{-6} \text{cm s}^{-1}$.^[7] The flux, F_d , by diffusion can be expressed by Fick's first law

$$F_d = -D_e b \frac{dc}{dr}$$

The $b = dC/dc$ is the soil buffer power defined previously. The C is the sum of the amount of nutrient in the soil solution and the amount of adsorbed nutrient that is able to replenish the nutrient in the soil solution spontaneously. Hence, b is the parameter mediating the effects of the soil chemical conditions on nutrient uptake by plants. D_e denotes the effective diffusion coefficient in the soil. D_e differs between media, but it can be related to the diffusion coefficient D_o for the nutrient in free soil solution. The influences of soil on diffusion, and thereby the relation between D_e and D_o , can be expressed by Eq. 3:^[10]

$$D_e = D_o \theta f / b \quad (3)$$

where θ is the volumetric water content expressed as a fraction, and f is the impedance factor that essentially allows for the increase in the actual diffusion distance because of the tortuous pathway of water filled soil pores and water films. The volumetric water content that allows a reasonable root activity is between 0.1 and 0.4. The value of f increases with increase in water content,^[11] whereas the buffer power remains constant with changes in soil moisture at the same bulk density.^[12] It has been observed^[13] that the relation between f and θ can be expressed empirically by $f = 1.58\theta - 0.17$ for $\theta > \text{about } 0.11$. From this it may be estimated that D_e decreases about 18 times if θ decreases from 0.40 to 0.15. Hence D_e is the parameter mediating the effects of soil moisture, soil chemical, and soil physical conditions on diffusion in soil.

Almost all studies on solute movement in the soil plant system neglect U in Eq. 2 because our understanding of the biology caused by root-induced processes and its effects on production or consumption of available nutrients is incomplete as yet.

To solve Eq. 2 for a given soil plant system is a complicated process, and in most cases, difficult or even impossible because of the lack of information on the soil root interactions and root behavior. The method for obtaining analytical and numerical solutions of Eq. 2 under a number of often simplified soil plant conditions has been summarized.^[6-8] However, illustration of the importance of diffusion for the bioavailability of nutrients in soils may be based on Eq. 4:

$$\Delta r = \sqrt{2D_e t} \quad (4)$$

in which Δr is the average distance of diffusion, e.g., in a direction normal to a root. The mathematics behind Eq. 4 has been presented by Jost.^[3] Based on Eq. 4, the equivalent soil volume (V in cm^3) of soil depleted for diffusible (available) nutrients—the quantity of bioavailable nutrients—can then be estimated as follows (Eq. 5) for roots without root hairs:

$$V = \pi(\Delta r + r_o)^2 L_v \quad (5)$$

in which Δr is estimated from Eq. 4, r_o is the root radius and L_v is the root density in cm cm^{-3} of soil. The data in Table 2 show the expected effective diffusion coefficient of a number of plant nutrients in soil and corresponding influences on the nutrient bioavailability; in addition, the data show how a decrease of the soil moisture from $\theta = 0.40$ to 0.15 affects the bioavailability at a root density of 5 cm^{-2} of roots without root hairs. It may be calculated from $f = 1.58\theta - 0.17$ and Eq. 3 that the diffusive flux decreases by a factor of $18 = D_e^{\theta=0.40} / D_e^{\theta=0.15}$. At field capacity of water content, the expected, effective diffusion coefficient of nitrate in soil is $10^{-6} \text{cm}^2 \text{s}^{-1}$. This is almost 10 times slower than in pure water. Hence, a pored media, such as soil, physically decrease the possibility for solute movement with a factor of nearly 10. As the soil dries out, this

Table 2 Expected effective diffusion coefficients of some nutrients in soil at field capacity of water content (e.g., $\theta = 0.40$), and estimated bioavailability as a fraction of diffusible (available) nutrient (Eqs. 4 and 5) at a root density ($L_v = 5 \text{ cm}^{-2}$) of roots without root hairs (mean root radius, $r = 0.01 \text{ cm}$; time, $t = 10$ days).

Element	$D_e^a \text{ (cm}^2 \text{ s}^{-1}\text{)}$	Bioavailable nutrient as a fraction of available nutrient ($V, \text{ cm}^3$)	
		$\theta = 0.40$	$\theta = 0.15$
Nitrate	1×10^{-6}	27.558	1.574
Potassium	1×10^{-7}	2.847	0.180
Boron	1×10^{-7}	2.847	0.180

factor increases as shown in Fig. 2. Apart from nitrate and chlorine, nutrient elements are adsorbed more or less to the solid soil constituents. This is the main cause of the decrease of the diffusion coefficients below $10^{-6} \text{ cm}^2 \text{ s}^{-1}$. The diffusion coefficient of phosphorus is as low as $10^{-9} \text{ cm}^2 \text{ s}^{-1}$ mainly because approximately 0.1% of the diffusible (available) phosphorus is dissolved in the soil solution only. This has a large effect on the bioavailability of the plant-available quantities of the various nutrient elements in soil as illustrated in columns 3 and 4 of Table 2. The V values ≥ 1 indicate that the root at a density of 5 cm^{-2} is able to deplete all the available nutrient as seen for nitrate, even under dry conditions, whereas only 4% of the available phosphorus is bioavailable inside

Fig. 2 Effects of soil and soil moisture on nutrient element mobility.

a period of 10 days. If the soil dries out to $\theta = 0.15$, the bioavailability decreases to only 0.6%. This illustrates that the decrease of soil moisture may create nutrient deficiency even in soil with high phosphorus fertility. However, phosphorus uptake is increased by the activity of root hairs (discussed in the following).

IMPORTANCE OF ROOT HAIRS

Root hairs are outgrowths from specialized root epidermal cells (trichoblasts). Root hair length, diameter, and number per unit length of root vary among plant species and genotypes within the same species.^[6,7,14] Frequency and size of root hairs are affected by many environmental factors, as well. In nature, the length of root hairs varies from 0.01 to 0.15 cm, the radius varies from 0.0005 to 0.002 cm, and the number per unit of length varies from 100 to 1000 per cm root. The importance of root hairs for phosphorus uptake has been demonstrated directly in the laboratory^[15,16] and under field conditions.^[14] It is reasonable to assume that the clusters of root hairs' outer tips form a fairly well-defined cylinder to which phosphorus diffuses, on average, a distance Δr in 10 days, and that root hair density and its period of function are long enough to withdraw the entire available nutrient in the soil penetrated by root hairs. The bioavailability of phosphorus, e.g., as affected by root hair length, can then be estimated from the following extension of Eq. 10:

$$V = \pi(\Delta r + \sigma + r_o)^2 L_v \quad (6)$$

in which σ is the root hair length in cm.

Fig. 3 shows that the bioavailability of phosphorus increases exponentially with the root hair length. Hence, root hairs play a very important role for the bioavailability of nutrients having a low effective diffusion coefficient (D_e) in soil.

BOUNDARY CONDITIONS AND NUTRIENT ENTRY

If depletion zones around the roots do not overlap, the solute concentration converges to the solute concentration c_b in the bulk solution, at which $F_T = F_m + F_d = 0$. The boundary conditions at the surface of the root are

$$F_T = F_m + F_d = \alpha c_o \quad (7)$$

in which $\alpha \text{ (cm s}^{-1}\text{)}$ is the root-absorbing power defined by Tinker and Nye^[6] and c_o is the concentration of solute at the root surface. It can be learned from Eq. 7 that the actual concentration (c_o) at the root surface and, therefore, the rate of nutrient flow per unit length of root, is determined by the ratio F_T/α . The kinetics of net uptake of nutrients^[7,17-19] may be expressed by:

Fig. 3 The effect of root hair length on phosphorus bioavailability. Soil moisture ($\theta = 0.4$); root density 5 cm^{-2} ; root radius 0.01 cm .

$$\overline{\ln L^*} = \frac{L^* \bar{I}_{\max} (c_o - c_{\min})}{K_m + c_o - c_{\min}} \quad (8)$$

in which L^* is the root length per unit of plant biomass, $\bar{I}_{\max}$ ($\text{mole cm}^{-1} \text{ s}^{-1}$) is the mean maximal net influx, K_m (mole cm^{-3}) is the Michaelis–Menten factor, c_o is the concentration of the nutrient at the root surface, and $c_{\min}$ is the nutrient concentration at which $\bar{\ln} = 0$. The values of the parameters $\bar{I}_{\max}$, K_m , and $c_{\min}$ vary according to the plant nutrient, temperature, and plant species/genotype and plant age. Furthermore, kinetics of nutrient uptake by roots may be influenced by ion interactions. Determined values of L^* , $\bar{I}_{\max}$, K_m , and $c_{\min}$ for uptake of several nutrients by several plant species or genotypes, obtained under conditions in which the rate-determining step of nutrient uptake was located in the roots, have been noted.^[20] The data show that the values of L^* , $\bar{I}_{\max}$, K_m , and $c_{\min}$ vary considerably among nutrients and among plant species and genotypes. This illustrates the efficiency by which these plants utilize soil as a source of nutrients. It is possible from $F_T = F_m + F_d = \alpha c_o$ and Eq. 8 to develop how α varies at varying solute concentration at the root surface by:

$$\alpha = \frac{\bar{I}_{\max} (c_o - c_{\min})}{2\pi r_o c_o (K_m + c_o - c_{\min})} \quad (9)$$

Figs. 4A and 4B illustrate the variation of α for phosphorus uptake at low concentration (c_o) at the root surface of some plant species and barley genotypes. Hence, the root-absorbing power (α) varies also at low concentration (c_o) of solute at the root surface. This implies that phosphorus uptake at low P concentration is more under the control of the plant parameters determining the size of α than under the control of P diffusion in the soil, whereas at the range of c_o at which α has achieved its maximum, uptake is controlled by diffusion.

Fig. 4 Absorption power (α) at varying phosphorus concentration at the root surface of some plant species (A) and barley genotypes (B).

CONCLUSION

Even though the movement—and the main factors affecting the movement—of nutrient elements to root by mass flow and diffusion is well known, the effect of soil conditions on crop growth is not properly understood. It is obvious that the big variation (Table 2) of the effective diffusion coefficient (D_e), caused mainly by the variation of the soil chemistry of the various nutrient elements, has a large impact on the bioavailability of nutrient elements. The mobility of phosphorus and micronutrients is so low in most soils that the soil exploited by root hairs is the main source of these elements. The root-induced modifications to the soil in the rhizosphere would then have a considerable impact on the efficiency by which plants use the rhizosphere soil as a source of nutrients. The understanding of how root-induced processes accelerate solute

movement and the transformation of non-available nutrients to bioavailable nutrients is increasing.^[6,21,22] Root hair length and root-induced processes appear to vary between genotypes of our crop plants.^[14] Hence, improvement of the efficiency by which plants use soil as a source of nutrients seems to be a possibility by targeted plant breeding.

Abstract

The soil–plant system is one of the most important components in agricultural and natural ecosystems. Nutrient dynamics in soil–plant systems not only reflect the pattern of nutrient flow but also influence food production and quality and the contaminant pathways in agricultural and natural ecosystems. In soil–plant systems, interactions between nutrients occur when the supply of one nutrient affects the movement, absorption, or utilization of another nutrient within the soil, soil–root interface (rhizosphere), or plant. There are several mechanisms of nutrient interaction in soil–plant systems. In this review, some specific examples are chosen to illustrate the mechanisms and effects of nutrient interactions, which include in the following: 1) nutrient interactions in soil; 2) nutrient interactions in the rhizosphere; and 3) nutrient interactions in plants.

NUTRIENT INTERACTIONS IN SOIL

Interactions between soil nutrients can occur through several soil physicochemical processes, particularly adsorption/desorption, dissolution/precipitation, and mineralization/immobilization. In these processes, nutrient interactions affect plant growth by affecting nutrient bioavailability. Adsorption and precipitation are the two key processes affecting nutrient interactions in soil.

Soil pH can affect the adsorption of nutrient ions and then affect nutrient uptake. The application of calcium carbonate (CaCO_3) can markedly increase the uptake of *molybdate* (Mo) by plants because the adsorption of MoO_4^{2-} by soils and by aluminum (Al) and iron (Fe) oxides decreases as pH increases due to CaCO_3 application. Additionally, interactions can also occur through the effects of one ion on the adsorption of another. For example, CaSiO_3 may displace dihydrogen phosphate (H_2PO_4^-) adsorbed onto Al and Fe oxides in soil. The application of H_2PO_4^- can increase Mo concentration in soil solutions by displacing MoO_4^{2-} from the surface of soil colloids. For cations, the *manganese* (Mn) oxides can readily adsorb cobalt (Co) from soil solution. The phosphates adsorbed by hydrous oxides of Fe and Al can further adsorb zinc (Zn). Interaction between H_2PO_4^- and Zn could occur through the formation of a complex between H_2PO_4^- and Zn on the surface of the oxides.^[1]

For precipitation effects, the application of CaCO_3 can decrease the toxicity of Al to plants by increasing soil pH

and thus forming precipitation of $\text{Al}(\text{OH})_3$. Factors that decrease soil pH can result in Al toxicity. Aluminum toxicity can also be modified by phosphorus (P) supply through forming a precipitate of AlPO_4 . Similarly, the concentration of Mn^{2+} in soil solution can be affected by the soil pH and oxidation–reduction potential. The availability of P for plants may be controlled by the dissolution and precipitation of Ca phosphates on calcareous soils and sparingly soluble Fe or Al phosphates on acid soils, which can also be modified by soil pH.^[2] Chloride or sulfate (SO_4^{2-}) can form stable complexes with cadmium ion (Cd^{2+}), thus increasing the concentration of *chloride* ion (Cl^-) or SO_4^{2-} in the growth medium can significantly increase plant uptake of Cd^{2+} .^[3]

NUTRIENT INTERACTIONS AND DYNAMICS IN THE RHIZOSPHERE

The rhizosphere is the narrow zone of soil adjacent to roots where root, soil, and microorganisms play joint roles. Therefore, the rhizosphere is regarded as a special habitat with intense nutrient interactions and biological activities. All mechanisms of nutrient interactions in bulk soil are also applicable to the rhizosphere, but some aspects of nutrient interactions in the rhizosphere are distinct from bulk soil due to specific rhizosphere processes. Only the effects of major rhizosphere processes on nutrient interactions are considered here.^[2]

Rhizosphere pH can affect adsorption–desorption and dissolution–precipitation of nutrient ions, thus affecting nutrient bioavailability to plants. Rhizosphere pH depends primarily on relative differences in root uptake of cations and anions. The supply of NO_3^- -N normally increases soil pH in the rhizosphere, whereas the supply of NH_4^+ -N decreases rhizosphere pH. Symbiotic nitrogen fixation by legume plants can decrease rhizosphere pH. Rhizosphere pH can also be decreased due to P deficiency for non-graminaceous species. This acidification can enhance the dissolution of sparingly soluble minerals containing P, K, Fe, Zn, and Mn.^[2]

The oxidation–reduction status in the rhizosphere plays an important role in nutrient interactions. The heavy precipitation of Fe^{3+} oxide hydrates can form a Fe film at the root surface due to the release of O_2 into the rhizosphere of rice, which severely hampers the uptake of other nutrients. An important factor for the decreased Mn^{2+} concentration in rhizosphere soil is adsorption of Mn^{2+} to the freshly precipitated Fe^{3+} oxide hydrates. In calcareous soils with low availability of both Fe and Mn, the response to Fe deficiency may thus overcome Mn deficiency to some extent, whereas in calcareous soils with low Fe and high Mn availability, this effect may cause excessive mobilization of Mn in the rhizosphere and Mn toxicity in plants.^[2]

Roots can release considerable amounts of organic substances into the rhizosphere. Phosphorus deficiency can increase the exudation of citrate in white lupin growing on P-deficient calcareous soils. Citrate has considerable effects on the mobilization of micronutrients and P in the rhizosphere. Citrate may contribute to both desorption and chelation of Al and Fe from Fe and/or Al phosphates and thus enhance P mobilization. Under Fe deficiency, phyto-siderophores are released from roots in grasses, which can form stable chelates not only with Fe^{3+} but also with Cu^{2+} , Zn^{2+} , and less distinctly with Mn^{2+} .^[2,4]

NUTRIENT INTERACTIONS IN PLANTS

Movement of nutrient ions from soil solution into the cell walls of individual cells or roots is the first step for nutrient uptake. The interaction between *silicon* (Si) and Al may reduce the toxicity of Al by producing low-solubility aluminosilicate on the root cell wall.^[5,6] Higher concentrations of Ca^{2+} in solution may depress the absorption of Zn^{2+} and Mn^{2+} and enhance the absorption of anions such as H_2PO_4^- and SO_4^{2-} , possibly through the modification of the surface electrical potential of cell walls. Increased concentrations of Mg and Ca in solution may protect plants

Fig. 1 Mechanisms and processes of nutrient interactions from soils to plants.

Source: Adapted from Robson & Pitman.^[1]

from Al toxicity by improving Mg or Ca nutrition and alleviating the toxic effect of Al on root development. Competition at absorption sites of root cell plasmamembranes is another mechanism for nutrient interactions. The absorption of MoO_4^{2-} by plant roots is strongly inhibited by SO_4^{2-} but is associated with an increase in H_2PO_4^- concentrations in solution. Nutrient interactions can also be operated through the regulation of efflux. For example, plants growing with higher external K^+ concentrations may have a higher efflux of Cs^+ than those growing with lower external K^+ concentrations, which contributes to the overall effect of K^+ – Cs^+ interactions.^[7] Altered expression of gene(s) related to the ion transport system of root cell plasma membranes may also be involved in nutrient interactions, e.g., P/Zn.

Another source of interaction among ions occurs due to the regulation of the cation/anion balance in cells. Nitrate ($\text{NO}_3\text{-N}$) and ammonium ($\text{NH}_4\text{-N}$) account for more than 70% of the total cations and anions taken up by plants. Iron nutrition of plants can be significantly improved by the supply of $\text{NH}_4^+\text{-N}$.^[8] Moreover, $\text{NH}_4\text{-N}$ supply could contribute to Fe translocation from primary leaves and roots to young leaves.^[2]

In nutrient utilization, the transport of one nutrient in xylem or phloem may be impaired by another nutrient. Furthermore, the function of the nutrient may be affected by this site.^[1] For example, Na^+ loading was larger than Mg^{2+} loading and was competed by K^+ . Chloride loading competed with SO_4^{2-} and phosphate. Additionally, high concentration of Ca or Mg may form precipitates in phloem, particularly in the presence of phosphates. The supply of Si can alleviate Mn toxicity in cereals by altering the distribution of Mn within plant leaves or regulating the uptake rate of Mn. However, the mechanisms for interactions between Si and Mn are not yet understood.

Nutrient interactions may occur during functioning of nutrients. For example, Mo is a constituent of nitrate reductase. When MoO_4^{2-} is replaced by WO_4^{2-} , the activity of NO_3^- reductase in higher plants can be inhibited. Some species can use Na in place of K for some, but not all, physiological or metabolic functions. Additionally, Mo, Ca, and Cu may be the components of the system of symbiotic N fixation.

Nutrient interactions can involve not only one mechanism but also several processes from soil to plant. For example, the mechanisms of interactions between Zn and P may include as follows: P depresses Zn bioavailability in soils and Zn absorption by roots and translocation of Zn from roots to shoots; P-induced growth response causes Zn dilution in plant tops; P–Zn imbalance leads to metabolic disorder; and P-activated interference affects Zn functioning. Additionally, P can also decrease the development of arbuscular mycorrhizas (AM), resulting in a decrease in plant Zn uptake mediated by AM.^[9] Overall, there is possibly a triangle interaction between P, Zn, and AM; however, the mechanisms involved are not clear.

CONCLUSION

Interactions between nutrients can occur through several different mechanisms involving nutrient movement from soil to root surface; nutrient dynamics in the rhizosphere; nutrient absorption and utilization by plants; nutrient mobilization and retranslocation within plants; and the expression of genes involved in nutrient uptake, translocation, and function (Fig. 1). It is important to identify the limiting step(s) of the overall effects of the interactions and what effects on plant growth are produced through nutrient interactions. Although some independent research on nutrient interactions in soils or plants has been done, systematic studies on nutrient interactions in the soil–plant system from molecular to ecosystem level should be emphasized in future research. Another dimension of nutrient interactions that needs attention is the control of plant uptake of trace elements (nutrients or contaminants) for food quality and environmental remediation.

Nutrients: Water Interactions

Ardell D. Halvorson

U.S. Department of Agriculture (USDA), Fort Collins, Colorado, U.S.A.

Abstract

Water plays a critical role in the availability of nutrients to plants. Adequate levels of both water and nutrients are needed to optimize plant growth and productivity. Fertilizer and water management practices can influence the efficient use of water and nutrients by plants and their subsequent impact on environmental quality.

INTRODUCTION

Water is a major factor in nutrient availability to plants.^[1–4] It is the vehicle through which nutrients move through soil to access plant roots for uptake. Nutrients move via mass flow and diffusion in soil water to the root surface. Root interception is a third way in which plants obtain soil nutrients as root hairs develop and contact the soil particles and/or solution.

WATER AND NUTRIENT AVAILABILITY

In mass flow, nutrient ions are transported with water flow to the root as the plant absorbs water for transpiration. Many mobile nutrients, such as calcium (Ca), magnesium, nitrate–nitrogen (NO₃-N), and sulfate, are transported to the root by mass flow. Diffusion of nutrients to the plant root occurs as ions move from high-concentration areas to low-concentration areas in the soil solution. Phosphorus (P) and potassium are two nutrients that move by diffusion.

If soil water becomes limiting, as it frequently does under dryland or rainfed conditions, nutrient availability to plants can be affected.^[5] Water is held as a film around soil particles. As the water content of the soil decreases, the thickness of the film decreases. Most plant nutrients are readily available when the soil is near field capacity, which is about the water content of the wet soil after two days of rain has saturated it and free drainage has ceased. Nutrient availability is at a minimum as the soil water content approaches the permanent wilting point, which is the water content at which plant roots cannot extract water from the soil. As soil water content diminishes, some less-soluble nutrients may precipitate out of the soil solution and become unavailable to plants. However, these minerals will dissolve and become available once again as the soil is rewetted. Thus, soil water content influences nutrient availability and plant growth.

Micronutrients are generally supplied to plant roots by diffusion in soil. Therefore, low soil moisture conditions will reduce micronutrient uptake. Plants require smaller quantities of micronutrients to optimize productivity than those of macronutrients such as P; thus, drought stress effects on micronutrient deficiency are not as serious as for P. However, iron and zinc deficiencies are frequently associated with high soil moisture conditions.^[2]

Soil water content is an important factor in microbial activity in soils. Soil microbial activity is important in the breakdown of organic plant and animal residues, which release nutrients such as N and P for plant uptake. Microbial activity tends to be the greatest when soil water is near field capacity with soil temperatures ranging from 25°C to 35°C. As soils dry, microbial activity decreases and lowers the rate of nutrient release from soil organic matter.^[6,7]

NUTRIENT AND WATER USE EFFICIENCY (WUE)

Adequate levels of plant nutrients are needed to optimize rooting depth and water extraction from the soil.^[2,3,5] Healthy plants tend to root deeper into the soil profile, using more of the soil water in the root zone. Thus, plants not only need adequate water to optimize yield potential, but also require an adequate level of nutrients to allow the crop to take advantage of the available water supplies. Under dryland conditions, the crop will often use all of the available water (precipitation plus soil water in the root zone) during the growing season. The application of N and P fertilizers will frequently increase crop yields, thus increasing crop WUE. WUE is the amount of crop produced per unit of available water from precipitation, soil, and irrigation. The influence of N fertilization on WUE of winter wheat, corn, and sorghum in a dryland wheat–corn or sorghum–fallow rotation is shown in [Fig. 1](#).

Fig. 1 WUE of wheat, corn, and sorghum as a function of N fertilizer rate in a dryland wheat–corn or sorghum–fallow rotation near Akron, Colorado, U.S.A.

When plant-available water is limited, the overapplication of N can also result in reduced grain yields owing to increased vegetative growth and water use in the early growth stage, with insufficient water remaining to maximize grain development and yield. The application of N will not increase yields without adequate plant-available water, and increasing plant-available water will not increase crop yield without adequate N supply. The percentage increase in response of crops such as wheat to P fertilization tends to be greater in dry years than in wet years on P-deficient soils, while both N and P are needed to optimize yields in wetter years.

Water is important for the activation and movement of fertilizer nutrients applied to soils.^[1–3,7,8] Dry fertilizer granules must dissolve in the soil water before they become available to plants. When applied to dry soil, liquid fertilizers may become unavailable to plants until precipitation or irrigation water rewets the soil and they become part of the soil solution again. Rainfall affects the volatilization loss of N from ammonia (NH₃)-based fertilizers such as urea and urea ammonium nitrate (UAN). Rainfall received within 36 hours after the surface applications of urea or UAN fertilizers will greatly reduce N volatilization losses and improve the N fertilizer use efficiency by crops. Rainfall moves the surface-applied N fertilizer into the soil where it can react and reduce NH₃ losses to the atmosphere. Excessive soil water, however, can result in anaerobic conditions and the loss of NO₃-N by denitrification. NO₃-N is converted to various N gases, which are lost to the atmosphere under anaerobic conditions.

Water is essential for optimizing crop yields. Under irrigation, water is generally not a yield-limiting factor. Under dryland or rainfed conditions, crop yields are dependent on available soil water supplies and growing season precipitation. Adequate levels of essential plant nutrients are

needed to optimize crop yields and WUE (i.e., kg grain produced/mm crop water use). Under rainfed conditions, crop water supplies during the growing season can vary weekly and annually. During the periods of drought (i.e., low supply of plant-available water), less plant nutrients are needed to optimize crop yields than during the years of average or above-average precipitation. In wetter years, both the crop yield potential and the nutrients needed to optimize crop yield increase.

Soil management practices, such as reduced- and no-till systems, that increase soil organic matter and improve soil physical quality also improve soil aggregation and porosity. This, in turn, improves water infiltration into the soil and water availability for increased crop productivity and improved nutrient use efficiency.

IRRIGATION WATER QUALITY AND FERTILIZER APPLICATION

Irrigation water quality can affect the application of fertilizer nutrients through irrigation systems.^[3,8] For example, the addition of anhydrous NH₃ or liquid ammonium polyphosphate fertilizers to irrigation waters high in Ca can result in the formation of lime and Ca phosphate precipitates. The precipitates can plug sprinkler and drip irrigation systems. In some instances, the precipitation of Ca can result in a higher sodium hazard of the irrigation water, which may subsequently reduce the water intake capacity of the soil.

Applying fertilizers with both flood and furrow irrigation systems requires that a uniform distribution of water be achieved throughout the field to obtain a uniform distribution of fertilizer nutrients to the crop. With flood and furrow irrigation systems, fertilizer should not be applied with the initial flush of irrigation water because of the generally non-uniform distribution of water during the initial wetting of the soil surface by the irrigation water. The reactions of fertilizers with the irrigation water and the fertilizer distribution to the crop are affected by (irrigation) water quality. If fertigation (i.e., the application of fertilizer nutrients through an irrigation system) is to be used, the compatibility of fertilizers to be applied with the quality of irrigation water available must be examined to avoid poor distribution of fertilizer nutrients.

ENVIRONMENTAL QUALITY

N is generally transported from soils into surface and groundwater by runoff, erosion, and leaching.^[7,9] Runoff water from watersheds with high levels of soluble N and P sources on the soil surface can contribute to the eutrophication of streams, lakes, ponds, bays, and estuaries. Placing or positioning applied N and P sources below the soil surface and using soil management practices to minimize

runoff will help reduce agriculture's impact on the eutrophication of water bodies. Water erosion of soil not only carries soluble plant nutrients from a watershed, but also carries soil particles with sorbed nutrients, such as P, into water bodies that can then contribute to the degradation of water quality.

Soil management practices such as no-till and other conservation tillage practices can reduce soil erosion by water. Water moving through soil in excess of field-capacity water content can move soluble nutrients, such as $\text{NO}_3\text{-N}$, below the root zone of crops and into groundwater. In summary, using cropping systems and an adequate fertility program to optimize crop WUE will help reduce loss of plant-available water and nutrients below the crop root zone.

CONCLUSION

Water plays a critical role in the availability of nutrients to plants. Adequate levels of both water and nutrients are needed to optimize plant growth and productivity. Fertilizer and water management practices can influence the efficient use of water and nutrients by plants and their subsequent impact on environmental quality.

Organic Agriculture

Kathleen Delate

Departments of Agronomy and Horticulture, Iowa State University, Ames, Iowa, U.S.A.

Abstract

Organic agriculture is based on minimal use of off-farm inputs and on management practices that restore, maintain, or enhance ecological harmony. The term “organic” is defined by law, but the labels “natural,” “eco-friendly,” and similar statements do not guarantee complete adherence to organic practices as defined by law.

INTRODUCTION

The USDA National Organic Standards Board defines organic agriculture as “an ecological production management system that promotes and enhances biodiversity, biological cycles, and soil biological activity.”^[1] It is based on minimal use of off-farm inputs and on management practices that restore, maintain, or enhance ecological harmony. The primary goal of organic agriculture is to optimize the health and productivity of interdependent communities of soil life, plants, animals and people.”^[1] The term “organic” is defined by law. The labels “natural,” “eco-friendly,” and similar statements do not guarantee complete adherence to organic practices as defined by law.

HISTORY

In 1990, the U.S. Congress passed the Organic Food Production Act (OFPA). This law was heralded as the first U.S. law established to regulate a system of farming. The OFPA requires that anyone selling products as “organic” must follow a set of prescribed practices that include avoidance of synthetic chemicals in crop and livestock production, and in the manufacturing of processed products. “Certified organic” crops must be raised on land to which no synthetic chemical (any fertilizers, herbicides, insecticides, or fungicides) inputs were applied for 3 years prior to the crops’ sale. Organic certification agencies became established in the United States to deal with a required “third-party certification.” There are at least 20 private certification agencies and 15 state agencies certifying organic production and processing in the United States. Proposed rules implementing the federal OFPA law were promulgated in 1997, after 7 years of revisions. Unfortunately, these rules did not meet private certification agencies’ standards, and a record number of complaints (275,000) were issued in the public comment period. The federal rules are established (released in 2001), all certifiers must utilize the federal standards as the minimum standard for the “certified organic” label in

the United States. European regulation is under the auspices of the International Federation of Organic Agriculture Movements with national certification agencies in each country.^[2] Japan certifies under the Ministry of Agriculture and Forestry. Certification for the European Union and Japan is extended to several U.S. certifiers that meet international standards.

Organic agriculture is the oldest form of agriculture on earth. Farming without the use of petroleum-based chemicals (fertilizers and pesticides) was the norm for farmers in the developed world until post-World War II (WWII). The war era led to technologies that were adapted for agricultural production. Ammonium nitrate used for munitions during WWII evolved into ammonium nitrate fertilizer; organophosphate nerve gas production led to the development of powerful insecticides. These technical advances since WWII have resulted in significant economic benefits, as well as unwanted environmental and social effects. Organic farmers seek to utilize those advances that yield benefits (e.g., new varieties of crops, more efficient machinery) while discarding those methods that have led to negative impacts on society and the environment, such as pesticide pollution and insect pest resistance.^[3] Instead of using synthetic fertilizers and pesticides, organic farmers utilize crop rotations, cover crops, and naturally based products to maintain or enhance soil fertility.^[4,5] These farmers also rely on biological, cultural, and physical methods to limit pest expansion and increase populations of beneficial insects on their farms. By managing their ecological capital through efficient use of on-farm natural resources, organic farmers produce for diverse and specialized markets that provide premium prices.

Because genetically modified organisms (GMOs) constitute synthetic inputs and pose unknown risks, GMOs, such as herbicide-resistant seeds, plants, and product ingredients, are disallowed in organic agriculture. Organic livestock, like organic crops, must be fed 100% organic food or feed in their production. Synthetic hormones and antibiotics are disallowed in organic livestock production. Traditional farmers throughout the world have relied on natural

production methods for centuries, maintaining consistent yields within their local environment. While “green revolution” technologies have led to increased yields in many less-developed countries, many farmers have seen an increase in pest problems with new varieties and high input-based systems.

Motivations for organic production include economic, food safety, and environmental concerns. All organic farmers avoid the use of synthetic chemicals in their farming systems, but philosophies differ among organic farmers regarding methods to achieve the ideal system. Organic farmers span the spectrum from those who completely eschew external inputs, create on-farm sources of compost for fertilization, and encourage the activity of beneficial insects through conservation of food and natural habitats, to those farmers who import their fertility and pest management inputs. A truly sustainable method of organic farming would seek to eliminate, as much as possible, reliance on external inputs.

WORLDWIDE STATISTICS

USDA does not publish systematic reports on organic production in the United States. The census in 1994 identified 1.5 million acres of organic production in the United States with 4050 farmers reporting organic acreage.^[6] This figure underrepresents production because many organic farmers opt to sell their products as organic without undergoing certification. The U.S. organic industry continues to grow at a rate of 20% annually. The industry was listed as a \$4.5 billion industry in 1998, with predicted future growth to \$10 billion by 2003. The organic industry is a consumer-driven market. According to industry surveys, the largest purchasers of organic products are young people and college-educated consumers. Worldwide consumption of organic products has experienced tremendous growth, often surpassing U.S. figures of 20% annual gain. Much of the increase in consumption worldwide has been fueled by consumers’ demand for GMO-free products. Because GMOs are disallowed in organic production and processing, organic products are automatically segregated as GMO-free at the marketplace. European consumers have led the demand for organic products, particularly in countries such as the Netherlands and Scandinavia. Two percent of all German farmland, 4% of Italian farmland, and 10% of Austrian farmland are managed organically.^[2] Prince Charles of England has developed a model organic farm and established a system of government support for transitioning organic farmers. Major supermarket chains and restaurants in Europe offer a wide variety of organic products in their aisles and on their menus. Industry experts predict that the establishment of federal rules will advance organic sales in the United States. Although the organic industry began as a niche market, steady growth has led to its place in a “segment” market since 1997. The organic dairy

industry, e.g., expanded by 73% from 1996 to 1997, and continues to grow. Organic markets can be divided into indirect and direct markets. Indirect or wholesale markets include cooperatives, wholesale produce operations, brokers, and local milling operations. Many supermarket chains buy directly from farmers or from wholesalers of organic products. Because meat can be labeled as “organic,” as of 1999, the marketing of organic beef, pork, chicken, and lamb has been significantly simplified. Roadside stands, farmers’ markets, and community supported agriculture farms constitute the direct marketing end of the organic industry. Most consumers relate their willingness to pay premium prices for food that has been raised without synthetic chemicals because of their concern for food safety and the environment. Supporting local family farmers also enters into their purchasing decisions.

CROP AND PEST PERFORMANCE IN ORGANIC SYSTEMS

The basis for all organic farming systems is the health of the soil.^[4,7] In addition to maintaining adequate fertility, organic farmers strive for biologically active soil, containing microbial populations required for nutrient cycling.^[8,9] Crop rotations (required for all organic operations) provide nutrients such as nitrogen in the case of legume crops (alfalfa and clover) and carbonaceous biomass upon which beneficial soil microorganisms depend on survival.^[10,11] A crop rotation plan is required as protection against pest problems and soil deterioration.^[12–15] Ideally, no more than four out of 6 years should be in agronomic crops, and the same row crop cannot be grown in consecutive years on the same land. Legumes (alfalfa, clovers, and vetches) alone, or in combination with small grains (wheat, oats, and barley), must be rotated with row crops (corn, soybeans, amaranth, vegetables, and herbs) to ensure a healthy system. A typical six-year rotation in the Midwestern United States would be corn (with a cover of winter rye)–soybeans–oats (with an underseeding of alfalfa)–alfalfa–corn–soybeans.^[16,17] Horticultural crops must be rotated with a leguminous cover crop at least once every 5 years.

Pest management in organic farming systems is based on a healthy plant able to withstand some pest injury and on the inherent equilibrium in nature, as most insect pests have natural enemies that regulate their populations in unperturbed environments.^[18,19] Because only naturally occurring materials are allowed in organic production, insect predators, parasites, and pathogens exist without intervention from highly toxic insecticides.^[20] Most organic farmers rely on naturally occurring beneficial insects on their farms, but some farmers purchase and release lacewings and other natural enemies every season, for example. There are also commercial preparations of natural insect pathogens, such as *Bacillus thuringiensis* (Bt), which are used to manage pestiferous larvae, such as corn borers. Botanical

insecticides, such as neem and ryania, are also allowable in organic production, but as with all insecticides, sprays should be used only as a last resort. Although these materials are naturally based, some materials may affect natural enemies. Prevention is a cornerstone of organic farming.^[21] Pest-free seeds and transplants, along with physical and cultural methods, are used to prevent pest infestations. Physical methods include the use of row covers for protection against insects such as cabbage butterflies and aphids. Cultural methods include sanitation and resistant varieties. Plant varieties are used that have been bred traditionally (i.e., no manipulated gene insertion or engineering involved) for insect, disease, and nematode resistance or tolerance.

Most organic farmers rely on multiple tactics for their weed management.^[22,23] Allelopathic crops, cultivation, mulching, and flame burning are all methods available for organic farmers. Allelopathic crops, such as rye and oats, produce an exudate that mitigates against small weed seed germination. Depending on the crop, cultivation offers the least labor-intensive method of organic weed management. Timely cultivation is key; without specific schedules, weeds proliferate. Propane flame burning is generally used in conjunction with cultivation, particularly during times of high field moisture. Mulching with straw or wood chips is commonly used in many organic horticultural operations.

Yields comparable to conventional crops have been shown for organic crops in three university long-term experiments in the United States (South Dakota State University,^[24] Iowa State University,^[16] the University of California-Davis,^[25] and in many European studies^[26]). Factoring in an organic premium (ranging from 50% to 400%, depending upon crop and season), organic systems consistently out-performed conventional systems in terms of economics.^[17,27,28] Pest problems were not a critical factor in these organic systems. Other studies have shown the benefits of organic practices, such as composting, in mitigating root-borne diseases.^[8]

KEY ISSUES REQUIRING ADDITIONAL RESEARCH

Continued verification of the long-term benefits of organic vs. conventional farming in terms of soil quality,^[29] pest management, and nutritional benefits^[30] is needed. Key issues include the development of management practices to increase nutrient cycling for maintenance of crop yields and optimize biological control of plant pests and diseases.^[31] Economic analysis, including risks of the three-year transition required for organic certification, will provide useful information for growers interested in alternative systems.^[26,32] Appropriate tillage systems, which protect soil quality and provide adequate soil preparation, are important issues for organic producers. The improvement of natural parasiticide formulations, such

as diatomaceous earth, is required for optimum organic livestock production. Marketing and support needs include the availability of reliable statistics for organic operations and prices. Although many European countries support their farmers in their organic production practices through environmental subsidies,^[33] the United States has made small gains in this area. Some state agencies (Minnesota Department of Agriculture) and the USDA Natural Resources Conservation Services through the Environmental Quality Indicators Program offer financial incentives to organic farmers during their transitioning years. More of these support services are needed to encourage farmers interested in the conversion to alternative production.^[34]

Organic Carbon: Assessment Methods

K.R. Islam

Ohio State University South Centers, Piketon, Ohio, U.S.A.

Abstract

Carbon, the principal component of soil organic matter (SOM), exerts profound effects on soil quality. A simple and rapid measurement of soil labile carbon by mild permanganate oxidation provides opportunities for early detection of changes in SOM quality. All available methods to determine soil organic carbon have inherent problems associated with them, and the user should select the method most applicable to the type of soils analyzed, expected recovery, and the required precision of the results.

INTRODUCTION

Soil organic matter (SOM), a complex, dynamic component of terrestrial ecosystem, is a core indicator of soil quality. Carbon (C) is the prime element present in SOM, comprising 48–58% of the total weight.^[1] Rapid and precise measurement of soil organic C (SOC) is essential to monitor temporal changes in SOM content. Since soil C is the sum of both organic and inorganic C pools, several methods have been developed or modified over years to determine SOC. The methods are: 1) dry and wet combustion analyses for total C and inorganic C separately and subtraction of the amount of inorganic C from the total C present; 2) dry and wet combustions for direct analysis of SOC after removal of inorganic C by acid pretreatment; 3) rapid dichromate oxidation of SOC from subsequent determination of unreduced Cr^{+6} or reduced Cr^{+3} by redox titration or colorimetric methods; 4) near-infrared reflectance spectroscopic analysis of SOC; and 5) rapid mild permanganate oxidation to measure soil active C by colorimetric method. A brief description of the measurement, principles, merits, and limitations of the commonly used methods for measurement of SOC is discussed (Table 1).

COMBUSTION METHODS TO MEASURE SOC AS CALCULATED FROM DIFFERENCE BETWEEN TOTAL C AND INORGANIC C DETERMINATIONS

Many of the total C methods are basic for the procedures modified to use for determination of SOC by dry and wet combustion methods. In dry combustion method, total C is measured in resistance or induction furnace using manual procedures or automated equipments.^[1,2] The use of resistance furnace to measure total C is based on oxidation of organic C from carbonaceous materials and thermal decomposition of carbonates with catalysts heating at about 1000°C in a stream of O_2 . In the use of induction furnace,

the soil sample is mixed with catalysts and rapidly heated to about 1650°C in a stream of O_2 to convert all C to carbon dioxide (CO_2). The CO_2 evolved is commonly trapped in Ascarite or suitable reagents and determined by titrimetric, gravimetric, volumetric, conductimetric, or colorimetric procedures. Using sequential dry combustion at different temperatures, both soil organic and inorganic C pools can be determined.^[6]

Most of the problems associated with the manual dry combustion techniques have been overcome by the development of automated combustion instruments. The widely used commercial instruments to measure total C are: LECO, Carlo-Erba, vario MAX CN, and Perkin–Elmer CHN analyzers. The citation of the above-mentioned instruments does not imply that they are superior or inferior to others in the market or being marketed.^[1,2] In automated dry combustion method, the soil sample is mixed with catalysts and heated in resistance or induction furnace in a stream of O_2 to convert all C to CO_2 . The CO_2 thus evolved is determined by gas chromatographic methods using thermal conductivity, infrared absorption, or flame ionization detectors.^[1,2]

The wet combustion of soil has long been a standard procedure for determination of total C. By using combustion train or Van Slyke–Neil apparatus, the soil sample is heated at about 210°C with a mixture containing $\text{K}_2\text{Cr}_2\text{O}_7$ – H_2SO_4 , and H_3PO_4 in a stream of O_2 to ensure complete oxidation of all C to CO_2 .^[7] The evolved CO_2 is determined gravimetrically, titrimetrically, or manometrically.

Determination of Soil Inorganic C (Carbonates)

Several methods are available for determination of soil inorganic C. These include: 1) neutralization of the carbonates with hydrochloric acid and back titration of the excess acid; 2) determination of calcium and magnesium in an acid leachate; and 3) dissolution of carbonates in

Table 1 Methodologies used for determination of organic and active C in soils.

Measurement	Basic methods	Principle	Merits	Limitations
From difference between soil total C and inorganic C	Both dry and wet combustions	Total C and inorganic C are determined on separate soil samples: $\text{SOC} = \text{total C} - \text{inorganic C}$	These methods yield reliable results for acid soils. Effective to oxidize resistant Cs. Automated methods are fast and precise	Two separate analyses are required. These methods are not suitable for high pH or recently limed soils. Incomplete thermal oxidation of carbonates
From determination of soil total C after removal of inorganic C	Both dry and wet combustions	Total soil C is determined after removal of inorganic C with acid pretreatment: $\text{SOC} = \text{total C}$	Total C measured after removing inorganic C is equal to SOC contents. Effective for acid soils	These methods are not very effective for complete removal of inorganic C
From rapid dichromate redox reactions	Wet oxidation	Dichromate (Cr^{+6}) oxidizes C in strong acid medium and the amount of Cr^{+6} reduced to Cr^{+3} is related to SOC	These methods are simple, rapid, and easy to use for a wide range of soils to measure SOC	Recoveries of SOC by the simple heat of dilution are incomplete and highly variable (60–86%)
a) Redox titration	Heat of dilution	Amount of Cr^{+6} reduced to Cr^{+3} is titrated with reducing agent and redox indicator	This method is rapid and simple to estimate C in different soils	Required a correction factor (1.32). Errors from variable C content in soils or horizons
With external heating	This is same as the Cr^{+6} oxidation procedure except that SOC is oxidized by external heat	No correction factor is required. The method, has reportedly permitted a total recovery of SOC	Errors due to thermal decomposition of Cr^{+6} . Interferences from Cl, Fe, and Mn oxides	
Colorimetric	Heat of dilution	Amount of oxidized Cr^{+6} or reduced Cr^{+3} species determined in solution is proportional to SOC	This is a simple and rapid method for SOC. No interferences from Cl, Fe, and Mn oxides	Low and variable recoveries of SOC from incomplete oxidation by simple heat of dilution
With controlled ionizing heating (e.g., hotplate)	This is same as the Cr^{+6} oxidation procedure except that SOC is assumed oxidized by external heating	This is a precise method with total SOC recovery. Minimum interferences from Fe, Cl, Mn, CO_3 , and charcoal	Thermal decomposition of Cr^{+6} due to ionizing heating; generates a substantial volume of wastes	
With nonionizing external heat (e.g., microwave oven)	This is same as the Cr^{+6} oxidation procedure except that SOC is assumed oxidized by nonionizing heating	This is a rapid, precise, and low-waste method. No interferences from Fe, Cl, Mn, CO_3 , and charcoal	A correction factor (1.09) is required. Need specialized equipments (e.g., microwave oven)	
From near-infrared reflectance spectrometry	Spectroscopic	SOC is determined from distinct spectral features of H–C bonds in SOM	This is a rapid and nondestructive method to measure SOC	Expensive and complex. Spectral responses affected by soil water, inorganic C, and total N
From permanganate oxidation of labile C	Wet mild oxidation	Amount of permanganate consumed is related to SOC from bleaching of pink color of the solution	Compared to SOC, the active C pool is more sensitive to management effects, and related to soil quality properties	The chemicals used are photosensitive and not stable over time. Yields best with dry soils

acid and determination of the inorganic C by measuring the volume or pressure of the CO₂ or by titrimetry, sample weight loss, infrared spectrometry, gas chromatography, and thermogravimetry.^[1,2]

COMBUSTION METHODS FOR DIRECT MEASUREMENT OF SOC AFTER REMOVAL OF INORGANIC C

Prior to direct measurement of SOC by dry or wet combustion method, inorganic C must be removed from soil, especially calcareous or limed soils. Soil inorganic C is removed by pretreating the sample with a mixture of dilute H₂SO₄ and FeSO₄ to minimize oxidation and decarboxylation of SOM or with H₂SO₃ followed by heating to remove H₂SO₃.^[7] It has been reported that inorganic C could be effectively removed by a metaphosphoric acid treatment at 130°C.^[8]

RAPID DICHROMATE OXIDATION METHODS FOR INDIRECT MEASUREMENT OF SOC

Previous works^[9,10] suggested that oxidation of SOC can be accomplished by a K₂Cr₂O₇–H₂SO₄ mixture as follows:

Over the years, a number of modifications^[11–13] have been proposed to measure SOC by rapid dichromate (Cr⁺⁶) oxidation methods (Table 1). The present variants of Cr⁺⁶ oxidation fall into two groups: one group is employed with simple heat of dilution and the another group is employed with external heat.

Rapid Titrimetric Determination of SOC After Dichromate Oxidation with Simple Heat of Dilution

Rapid titration methods to measure SOC are based on simple heat of dilution from K₂Cr₂O₇–H₂SO₄ mixture. The amount of Cr⁺⁶ remaining after oxidation is back titrated with ferrous ammonium sulfate in the presence of redox indicators.

Rapid Titrimetric Determination of SOC After Dichromate Oxidation with External Heating

A controlled use of external heating to oxidize C by K₂Cr₂O₇–H₂SO₄ mixture under reflux with two reagent blanks was suggested for complete recovery of SOC.^[11,13] One blank is used for standardization of the ferrous ammonium sulfate due to variable stability, and the another, a boiled blank to account for thermal decomposition of the

Cr⁺⁶. This method has been widely used with modifications to perform digestion in Folin–Wu tubes placed in an Al-heating block at 150°C^[14] or digestion of soil with K₂Cr₂O₇–H₂SO₄ mixture for 30 minutes in glass tubes in a heating block at 170°C.^[15] Others suggested that digestion of soil sample with a mixture of K₂Cr₂O₇–H₂SO₄ at 135°C is optimum for complete oxidation of SOC.^[16] The remaining Cr⁺⁶ is back titrated with ferrous ammonium sulfate in the presence of redox indicators.

Colorimetric Determination of SOC After Rapid Dichromate Oxidation with Simple Heat of Dilution or External Heating

The Cr⁺⁶ oxidation methods with or without external heating for measurement of SOC have been modified colorimetrically after removal of soil particles from the suspension by filtration or centrifugation.^[3,17–19] As the oxidation of SOC is accompanied by the reduction of Cr⁺⁶ to Cr⁺³, a pronounced change in color, orange to green, provides a rapid colorimetric measurement of SOC that is preferred over the tedious titration procedures.^[3,17–19] The Cr⁺³ exists as stable hexaquo ion [Cr(H₂O)₆]⁺³ in an acid medium and has two absorption peaks at 450 and 590 nm, respectively.^[18] In a comparison of methods that used to measure Cr⁺³ and Cr⁺⁶ absorption, it has been suggested that colorimetric detection of Cr⁺³ green color intensity in K₂Cr₂O₇–H₂SO₄–soil mixture at 590–600 nm wavelengths, without any masking interference from Cr⁺⁶, is proportional to the amount of SOC.^[18,19] An external heating at 135°C for 30 minutes is enough to oxidize C by Cr⁺⁶ for colorimetric determination of SOC from Cr⁺³ concentration measured at 600 nm against sucrose C standards.^[19]

Since the heat of dilution raised the temperature of K₂Cr₂O₇–H₂SO₄–soil mixture sufficiently to induce a substantial oxidation within a minute or so, a rapid colorimetric method based on nonionizing microwave energy has been developed for improved oxidation to determine SOC.^[3] The rapid microwave energy supplemented K₂Cr₂O₇–H₂SO₄ soil digestion followed by colorimetric measurement of Cr⁺³ absorption at 590 nm provides a reliable measurement of SOC. The results obtained by the rapid microwave energy supplemented colorimetric method are significantly accounted for 99.2% variations in SOC content (Fig. 1) measured by the LECO dry combustion method.^[3]

NEAR-INFRARED REFLECTANCE SPECTROSCOPIC (NIRS) ANALYSIS OF SOC

The NIRS measurement of SOC based on distinct spectral features of H–C, C–N, and H–O bonds in SOM within the visible and near-infrared regions of the spectrum.^[4,20] It has been reported that NIRS can be used

Fig. 1 Relationship between SOC measured by a rapid microwave digestion method and the LECO dry combustion method. **Source:** From Islam & Weil.^[3]

to measure independently and simultaneously SOC, inorganic C, and total N for soils with diverse C and N compositions.^[4]

COLORIMETRIC DETERMINATION OF SOIL LABILE OR ACTIVE C AFTER PERMANGANATE OXIDATION OF SOIL

Changes in small but relatively labile fractions of SOC may provide an early indication of soil quality in response to management practices.^[5,21–23] Most research on labile C has used the 0.333 M KMnO_4 to oxidize a fraction of soil C considered biologically active.^[5,21–23] A highly simplified colorimetric method has developed to determine active C after 2 minute shaking of air-dried soil with neutral dilute solutions (0.02–0.025 M) of KMnO_4 provides reliable and consistent results in response to soil management practices.^[5] Results from the 0.02 M reactive labile C significantly accounted for 81% variations in SOC content (Fig. 2) determined by LECO dry combustion method.^[5]

CONCLUSION

C, the principal component of SOM, exerts profound effects on soil quality. Among the methods used to determine SOC, automated dry combustion method provides an accurate measure of SOC over other methods. The developments in rapid dichromate oxidimetric, colorimetric methods that involve refluxing under external heating provide SOC values comparable to those obtained by automated dry combustion methods. A simple and rapid measurement of soil labile C by mild permanganate oxidation provides opportunities for early detection of changes in

Fig. 2 Relationship between soil active C measured by a rapid permanganate oxidation method and the SOC measured by the LECO dry combustion method. **Source:** From Weil, Islam, et al.^[5]

SOM quality. All available methods to determine SOC have inherent problems associated with them, and the user should select the method most applicable to the type of soils analyzed, expected recovery, and the required precision of the results.

Organic Carbon: Sequestration Concepts

Kenneth R. Olson

*Department of Natural Resources and Environmental Sciences,
University of Illinois at Urbana-Champaign, Urbana, Illinois, U.S.A.*

Abstract

One source of the conflicting soil organic carbon (SOC) sequestration findings relates to the general nature of the definition of SOC sequestration. The sequestered SOC process should increase the net SOC stock at the end of a study to above the pretreatment SOC stock baseline and result in a net reduction in the carbon dioxide (CO₂) levels in atmosphere. In agricultural land areas, no-tillage (NT) systems have been proposed to replace moldboard plow and chisel systems as a way to sequester SOC. Numerous estimates have been published on SOC sequestration rates as a result of a switch to NT systems. For SOC sequestration to occur as a result of a treatment applied to a land unit, all of the SOC sequestered must have come from atmosphere and be transferred into the soil humus through the unit plants, plant residues, and other organic solids. To unequivocally demonstrate that SOC sequestration at a specific site has occurred, a temporal increase must be documented relative to pretreatment SOC level and linked to a net depletion of atmospheric CO₂.

INTRODUCTION

The increase in atmospheric levels of carbon dioxide (CO₂) has been largely due to the burning of fossil fuels, deforestation, cultivation of the grasslands, drainage of the land, and land use changes. This has led to an increase in greenhouse gases (GHGs) and created concerns about the potential for long-term climate change and interest in developing methods to sequester some of this atmospheric carbon (C). In agricultural land areas, no-tillage (NT) systems have been proposed to replace moldboard plow (MP) and chisel plow (CP) systems as a way to sequester soil organic carbon (SOC). Numerous estimates have been published on SOC sequestration rates as a result of a switch to NT systems. Other researchers have proposed the use of cover crops, synthetic fertilizers, organic fertilizer, manure, liming, agricultural systems and management, agroforestry, forages, compost, crop rotations, and reduced row crop use as ways to sequester SOC. The amount of SOC present in the soil humus at the end of the study has to be greater than the pretreatment SOC levels in the same land unit, and as a result, there needs to be a net depletion of atmospheric CO₂. One source of the conflicting SOC sequestration findings relates to the general nature of the definition of SOC sequestration. The sequestered SOC process should increase the net SOC stock at the end of a study to above the pretreatment SOC stock baseline and result in a net reduction in the CO₂ levels in atmosphere. In agricultural land areas, NT systems have been proposed to replace MP and CP systems as a way to sequester SOC. Numerous estimates have been published on SOC sequestration rates as a result of a switch to NT systems. For SOC

sequestration to occur as a result of a treatment applied to a land unit, all of the SOC sequestered must have come from atmosphere and be transferred into the soil humus through the unit plants, plant residues, and other organic solids. When claiming that SOC sequestration at a site has happened, a temporal increase must be measured relative to pretreatment SOC stock and linked to a net reduction in the atmospheric CO₂.

Application of the SOC Sequestration Concept to a Specific Site

One source of the conflicting SOC sequestration findings relates to the general nature of the definition. SOC sequestration was defined by Olson^[1] as a “Process of transferring CO₂ from the atmosphere into the soil of a land unit through unit plants, plant residues and other organic solids, which are stored or retained in the unit as part of the soil organic matter (humus).” The retention time of sequestered C in the soil (terrestrial pool) can range from short-term (not immediately released back to atmosphere) to long-term (millennia) storage. The sequestered SOC process should increase the net SOC storage during and at the end of a study to above the previous pretreatment baseline levels and result in a net reduction in the CO₂ levels in atmosphere. The land unit concept with borders was added to the definition previously proposed by Olson^[2] to add clarity and to prevent the loading or adding SOC stocks to the land unit soil naturally or artificially from external sources without accounting for the C additions. C not directly from the atmosphere and from outside the land unit should not be counted as sequestered SOC. These external inputs could

include organic fertilizers, manure, plant residues, and topsoil or natural input processes such as erosion of a sloping soil and sediment-rich C deposition on a soil located on a lower landscape position or in a waterway. The land unit could be a plot, plot area, parcel, tract, field, farm, landscape position, landscape, wetland, forest, or prairie with defined and identified boundaries. This entry only discusses SOC sequestration as defined in the proposed definition and not soil inorganic carbon (IC), OC, or C sequestration.

Atmospheric C is cycled to the plant by photosynthesis, the plant cycles the organic C to the soil as residue, and it becomes humus or soil organic matter (SOM). It is impossible for most researchers, with the possible exception of modelers, to quantify changes in both the terrestrial and atmospheric pools. Therefore, the soil sequestration definition needs meaningful boundaries to be used by the researchers who want to measure actual changes in a specific part of a terrestrial (soil) pool.

Determination of Long-Term SOC Levels and Trends in Agricultural Lands

U.S. researchers have reported that the SOC content of timberland and prairie soils declines by 20–30% with cultivation.^[2,3] Rapid losses frequently occur in the first few years after clearing and cultivation; land drainage and land use change can result in additional SOC losses for many more years with the most significant being within the first 5–40 years.

Depth Distribution of SOC (Surface Layer vs. Root Zone)

When determining SOC sequestration, storage, and retention, it is important to include the entire root zone commonly to a depth of 1–2 m unless there is a root-restricting layer present, such as a fragipan or bedrock. Some tillage systems can enhance the SOC storage or retention in the surface and subsurface layers while decreasing it in the subsoil layer. The SOC needs to be totaled for the entire

root zone. Most soil sampling techniques use distance from the soil surface as a primary metric. Deep SOC profiles can differ between tillage and other treatments.

Identify Appropriate Experimental Designs for Use in Determining SOC Sequestration

Much of the literature^[4–8] suggests that paired comparison method, among various tillage treatments with one treatment, such as MP, used as baseline or control can be used to determine SOC sequestration rates. These comparison plots are often sampled only once during or at the end of a long-term study to determine the rate of SOC sequestration (Table 1). These researchers apparently assumed that the treatment used as baseline (often MP) at the end of a study had the same SOC stock it had prior to the treatment application or at the start of a long-term study. The MP baseline level of SOC was then maintained at a steady state during the study. If true, then any increase in SOC of the comparison treatment (NT) above the baseline treatment (MP) at the end of study would represent the amount of SOC sequestered (Table 1). However, these studies often lack or do not report the pretreatment SOC stock of the baseline treatment.^[2,9] Without such pretreatment SOC data for the baseline treatment (MP), the NT SOC sequestration rate findings cannot be verified.^[2,10]

If SOC in comparison treatment (NT) at the end of experiment was higher than that in the baseline treatment (MP) before the tillage treatments were applied, then SOC sequestration occurred. Alternatively, when the comparison treatment (NT) did not have more SOC stock at the end of the study than the baseline treatment at the start and the end of the study, then no SOC sequestration occurred. If the SOC sequestration rate is based on an NT comparison with SOC stock of the baseline treatment (MP) in the final study year^[11] when baseline treatment is not at a steady state, findings might not be correct (Table 1). It is possible that all treatments including baseline treatment (MP) lost SOC over time, and if so the differences between treatments at the end of the study only mean that one treatment (NT) lost

Table 1 Twenty-year effects of tillage treatments on the net SOC stock ($\text{Mg C ha}^{-1} \text{ layer}^{-1}$) amount of difference and SOC retention rate differences on the Grantsburg soil using the paired comparisons method.

Tillage treatment (six replications)	Depth (cm)	June 2009 SOC stock after 20 years of treatment ($\text{Mg C ha}^{-1} \text{ layer}^{-1}$)	June 2009 comparison method with SOC retention difference between NT and MP ($\text{Mg C ha}^{-1} \text{ layer}^{-1}$)	Paired comparison method with MP as baseline, NT vs. MP 20-year total SOC retention rate above 2009 MP baseline ($\text{Mg C ha}^{-1} \text{ layer}^{-1} \text{ yr}^{-1}$)
NT	0–15	25.2a	+7.9	0.40
	15–75	20.1a	+1.2	0.06
	0–75 (all)	45.3a	+9.1	0.46
MP	0–15	17.3b		
	15–75	18.9a		
	0–75 (all)	36.2b		

Note: Mean of six replications with the same letter in the same year and depth with a different tillage treatment is not significantly different at $P = 0.05$.

less SOC or retained more SOC in storage or is losing SOC at a lower rate (Table 1). When the pretreatment SOC for baseline treatment (MP) at the beginning of the long-term experiment is higher than at the end, no SOC sequestration can be claimed for any other comparison treatment (NT) without subtracting this baseline treatment SOC stock decrease from NT.^[1,2]

Develop a Procedure with Pretreatment Measurements of SOC Levels

The use of the comparison method with MP as baseline without establishing the pretreatment SOC content of the baseline treatment before the establishment of experiment could, in some cases, overestimate the amount of SOC sequestration, i.e., the SOC sequestration rate, and underestimate the amount of GHG released to the atmosphere from SOC during the study. SOC losses can occur from water erosion, MP tillage mixing, disturbance during planting in NT, disturbance when nitrogen (N) injection occurs in corn (*Zea mays* L.) years, aeration, and mineralization. This can and often does offset the SOC gains from plant and root growth and residue being returned to the humus or SOM.

Previously eroded soils with low SOC content were identified as having significant potential to sequester SOC.^[8,12] For 20 years, Olson^[2] studied previously eroded soils on 6% slopes with low SOC stocks in an attempt to quantify the amount and rates of SOC storage and retention as a result of a conversion to NT system. Pretreatment SOC baseline of the plot area was used to determine SOC loss from NT and MP plots.^[2] No SOC sequestration actually occurred in the NT and MP plots since the SOC level of the plot area was higher at the start of the experiment than at the end of the study.^[2] The NT plots did retain or store more SOC after 20-year tillage study than MP plots (Table 1). However, there was no increase in sequestered SOC in NT system.^[1,2]

Findings suggest that a pretreatment SOC baseline is essential in all tillage studies to determine the amount and rate of SOC sequestration, steady state, and loss. A pretreatment SOC baseline was needed in these tillage studies when determining the amount and rate of SOC sequestration, storage, retention, and loss, especially on sloping and eroding soils with more intensive cropping rotations (more row crops and fewer years of forages) during the study than in years preceding the study. Clearly, MP treatment was not at steady state during the 20-year tillage experiment.^[1,2] In fact, MP plots lost 15.2 Mg C ha⁻¹ from the root zone as a result of mixing, intensity of crop rotation, aeration, and eroded SOC-rich sediments being transported off the plot area.^[2] NT treatment only reduced the magnitude and rate of SOC loss over time. The pair comparison method used by many researchers with MP as baseline suggested that +9.1 Mg C ha⁻¹ of SOC sequestration occurred (Table 1) during the 20-year experiment. However, the 1988 baseline method did not validate the SOC sequestration rate.^[2] At

this site, the sloping and eroding NT plot actually lost 6.8 Mg C ha⁻¹ during the 20-year study, so no actual SOC sequestration occurred.^[2] The assumption that the MP was at a steady state, made by researchers using the comparison method with 1 year of SOC sampling near the end, was incorrect and resulted in a SOC sequestration finding that was invalid.^[2]

It is true that if a researcher had decided to use MP instead of NT, the amount of SOC retained in the soil after 20 years of MP treatment^[2] would be significantly less (−9.1 Mg C ha⁻¹) than after 20 years of NT treatment, and therefore, the GHG emissions from the SOC in storage or retained in the NT plots would be lower than those from the SOC in storage or retained in the MP plots. During the 12-year experiment, the SOC stocks in the subsoil and for the entire root zone increased by 2012 under the NT, CP, and MP systems with cover crops (Table 2). The SOC of the 0–15 layer increased under NT but not under CP and MP. By 2012, cover crop treatments raised SOC stocks significantly for the rooting zone of all tillage treatments except CP. Using the pretreatment baseline 2000 SOC stocks, NT, CP, and MP with cover crops sequestered SOC in root zone.^[13] The results shown in Table 2 illustrate how the pretreatment method can be used to validate the SOC findings.

To determine whether SOC sequestration has occurred, it is critical that researchers establish the baseline SOC stock prior to any treatment applications including cover crops. NT, CP, and MP treatments with cover crops did sequester and maintain more SOC stocks above the 2000 pretreatment baseline levels. The SOC gains from cover crops were equal to or more than any loss from any disturbance or mixing during planting, N injection in corn years, and erosion during corn and soybean production. SOC sequestration occurred in root zone (0–75 cm) for all of the tillage treatments with cover crops which were compared with 2000 pretreatment SOC stock levels (baseline) which validated the findings.

Rate of SOC Stock Change

It is not possible to determine a rate of change if all the data are collected at one time and near the end of the study. A rate of change study requires the sampling at two or more different times during the length of the study. The way some researchers get the rate of change is by assuming that the SOC stock for the baseline, usually MP, is at a steady state. That allows the researcher to assume that the SOC of the MP plots was the same before and after the tillage treatment application. Then, the NT gain above the baseline (MP) in measured year is divided by the number of years since the start of experiment to get the SOC sequestration rate.

Baseline Steady-State Assumption

All of these land use and agricultural system changes over time have had an impact on the SOC levels and trends (gains,

Table 2 Use of pretreatment 2000 SOC stock values for each tillage plot as baseline to determine the total SOC change in 12-year cover crops for the Grantsburg soils.

Cover crops by tillage treatment	Depth (cm)	September 2000 SOC stock (Mg C ⁻¹ ha ⁻¹ layer ⁻¹)	June 2012 SOC stock (Mg C ⁻¹ ha ⁻¹ layer ⁻¹)	12-year tillage effect on SOC total change by treatment using baseline		12-year tillage effect on SOC rate of change

steady state, and loss) in the United States. Each change affected the SOC stocks and trends. Some management practices raised the SOC levels and some lowered them, but the SOC of the soils seldom reached a true “steady state” since many of these land use and practice changes were adopted at various times and had an impact over different time periods. It usually takes years to reach a steady state, especially if the soils are sloping and eroding, and SOC-rich sediment is being transported from the land unit.

Microbial Role in SOC Sequestration, Net Storage, or Retention Rate Change over Time

The primary reason that SOC sequestration amounts and rates are often overestimated in tillage and management systems is a result of enhanced microbial activity over time. During the decomposition process, the C in the residue and some of the SOC in storage are released to the atmosphere as CO₂. This release rate of CO₂ can be accelerated over time, as more residue and amendments are added to the soil. During a long-term experiment of 20–50 years, much of the SOC formed in early years of the study will be released before the end of the experiment. If net SOC storage is increased in the 1st year at a rate of 0.5 Mg C ha⁻¹ yr⁻¹, the rate will drop the next year as a result of microbial activity. The 2nd year's net gain (0.5 Mg C ha⁻¹ yr⁻¹ rate) would be the same as in the 1st year, but the 1st year's rate will be reduced by the microbial release of some of the 1st year's SOC storage and effectively lower the annual rate for the 1st year. This will happen each year with some of the previous year's net SOC storage being released in the subsequent year as a result of water erosion, mixing by tillage,

disturbance during planting, microbial activity, when crop rotation is intensified, when synthetic N is injected, aeration, and mineralization, which would effectively lower the net annual SOC sequestration rate in a long-term study.

Account for the Loading of C-Rich Amendments

The loading of C-rich amendments by researcher or the natural deposition of SOC-rich sediment^[2,9] from outside the land unit needs to be accounted for when claiming SOC sequestration. The proposed definition of SOC sequestration requires that the land unit used has specified boundaries and only C gains from the atmosphere to the soil humus to be based on C inputs from the land unit plants and roots and their residue only. Any loading of external C-rich amendments (not directly from the atmosphere through unit plants to the soil humus) such as manure and organic fertilizers must be accounted for in the analysis and should be deducted from the amount claimed as SOC sequestration since it was not created in the land unit and did not lead to a reduction in the atmospheric CO₂ levels. The treatment applied could still result in SOC sequestration. The C loading on a land unit would most likely increase the amount of CO₂ given off, from the land unit during decomposition to the atmosphere even if some additional humus formation were to occur in the land unit as a result of the C loading.

The loading of C-rich amendments from an external source onto a land unit creates a number of issues. Some researchers will want to claim part of the C-rich amendment as sequestered SOC. This could be in the form of OC amendments (manure, saw dust, or organic fertilizers), IC

amendments (lime or dolomite), and SOC amendments (new topsoil or sediment deposition). These amendment cases illustrate the necessity of specifying the land unit and origin of the C sources in order to accurately measure the change in SOC derived from the atmosphere. This specification prevents the loading of C-rich amendments from outside the land unit boundaries and claiming the C additions as SOC sequestration when the SOC was not sequestered in the land unit and the atmosphere was not depleted of CO₂ as a result. The addition of land unit boundaries in the definition of SOC sequestration prevents the overestimation or underestimation of SOC sequestered by C loading. The C-rich amendments from external sources could in some cases eventually raise the land unit humus or net SOC storage levels, but that C addition to the humus was not sequestered SOC and may increase GHG emissions.

CONCLUSION

It is important to determine SOC sequestration rates for various agricultural land treatments and to establish a protocol to validate the amount and rate of SOC sequestration. Previous soil science research has built an important beginning foundation to assess the capacity of soil to store and sequester C. However, there are inconsistencies and errors in the application of SOC sequestration concept, plot area experiment designs, and depth of measurements. Most critical is the inability to accurately verify C drawn from the atmosphere and sequestered in the soil. Land unit boundaries need to be incorporated into the definition of SOC sequestration when applied to a specific site that pretreatment baseline measurements are essential to all studies, and that field experiments be designed to more carefully measure, monitor, and assess internal and external inputs. That amount of SOC loss from the soil storage during the time of experiment needs to be subtracted from SOC sequestration amount to determine the change in net SOC storage. The proposed protocols that have been discussed earlier are necessary to move the science forward and to attempt to address climate trends. The amount of SOC sequestered as a result of alternative agricultural systems such as NT and its effects on the net SOC storage changes in terrestrial pool and SOC released where the water and atmospheric pools need to be measured or calculated. If the losses from the terrestrial pool are greater than the gains in SOM during the time of the experiment, then no net SOC

sequestration would have occurred, and the release of CO₂ gas would have increased rather than being depleted in the atmosphere.

Organic Carbon: Subsoil Pools

Klaus Lorenz

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Routine soil surveys are restricted to about 1 m depth but more soil organic carbon (SOC) is stored globally below this depth (1325 Pg C to 1 m depth vs. 3000 Pg C to soil profile depth). Deposition of carbon (C) from roots and associated biota is the main subsoil C input and inevitable where deep soils coincide with deep rooting. The SOC at depth is characterized by slow turnover times, as environmental conditions in subsoil are less favorable for decomposition, and a range of physical and biological mechanisms stabilize SOC. Thus, subsoil SOC sequestration can contribute to climate change mitigation. However, SOC in subsoil may also respond dynamically on decadal timescales to environmental change, and more research is needed on this poorly understood pool of the contemporary C cycle.

INTRODUCTION

Soils comprise the largest pool of organic carbon (OC) in the terrestrial biosphere. The vertical distribution of soil organic carbon (SOC) within soil profiles is, however, unclear. In the subsoil below 30 cm depth, soil organic matter (SOM) stocks and fluxes are crucial for the soil functions. Aside from storing soil inorganic carbon and SOC, the subsoil contributes to the cycling of elements with consequences, e.g., for groundwater chemistry, in plant nutrition. Despite lower concentrations, the subsoil is probably also an important factor for the long-term storage of SOC, as the radiocarbon age and turnover time of organic matter (OM) increase with increase in soil depth. Associations of OM with pedogenic minerals (i.e., mineral–organic associations) result in the long-term stabilization of OC especially in the subsoil. In the deep soil profile, environmental conditions are detrimental to decomposition. Increases in the relative amount of mineral-associated carbon (C) compared to C relatively free of mineral particles at depth may contribute to SOC stabilization. The OM in the subsoil has therefore the potential to contribute to the mitigation of atmospheric increases in carbon dioxide (CO₂) by SOC sequestration.

SOURCES OF SUBSOIL OC

Among sources of subsoil OC are surface residues incorporated into the mineral soil by physical mixing and solubilization, transport, and subsequent adsorption.^[1]

Soil burial by volcanic, aeolian, alluvial, colluvial, glacial, and anthropogenic depositional processes also contributes to deep SOC storage.^[2] However, plant roots (i.e., litter and rhizodeposition) are the primary vector for most C entering the subsoil.^[3] The relative importance of surface residue incorporation vs. root litter and rhizodeposition for profile SOC distribution and dynamics depends on climate, soil, and vegetation types.^[4] Residues of plant litter decomposition, SOM, and compounds released by microorganisms are the major sources of water-soluble organic C. The dissolved organic carbon (DOC) is transported from upper to deeper soil layers with the percolating water. The organic C contained in the soil aqueous phase represents a pool of highly mobile, predominately solvated molecular fragments of relatively small molecule size.^[5] With increasing depth, DOC may be strongly adsorbed to poorly crystalline iron and aluminum (hydr)oxides with a high specific surface area resulting in the stabilization of OC.^[6] In contrast to studies in temperate forest soils, there are only a few studies on DOC in temperate arable and grassland soils and in tropical agroecosystems.^[7] For example, the process of DOC movement and retention was responsible for 9% of the total SOC pool to 1 m depth in a temperate grassland soil.^[8] The soil fauna (i.e., earthworms, ants, and termites) translocate OM to deeper soil layers by burrowing activities.^[9] In particular, earthworm activity may be of great significance to the long-term stabilization of OM in the soil.^[10] However, the major determinant of the relative distribution of SOC with depth is probably the allocation of net primary productivity

Table 1 Global rooting depths and vertical distribution of SOC.

Parameter	Grasses/grasslands	Shrubs/shrublands	Trees/forests	References
Maximum rooting depth	15.0 m	5.2 m	7.3 m	[12]
Additional SOC in 1–2 m relative to 0–1 m	0.30	0.38	0.29	[11]
Additional SOC in 2–3 m relative to 0–1 m	0.13	0.39	0.27	[11]

belowground as root litter and rhizodeposition.^[3] Thus, the vertical root distribution leaves distinct imprints on the depth distribution of SOC (Table 1).^[11] Roots (and their associated biota) contribute more C to SOM than aboveground residues. Because of their maximum rooting depths, grasses and trees transfer C to considerably deeper soil layers than shrubs, with maximum rooting depths of 68 m.^[12]

COMPOSITION OF SUBSOIL OC

The composition of the belowground plant and microbial C input to SOC may be substantially different from that of the aboveground input.^[13] However, beyond the decadal time frame, selective preservation of relatively unaltered plant-derived compounds due to biochemical recalcitrance (i.e., aliphatic compounds such as lipids and waxes) may not be as an important long-term stabilization mechanism as previously thought.^[14,15] Similarly, microbial-derived OM may not be recalcitrant or composed of complex compounds, as mean residence times of microbial biomarkers in soils do not exceed several hundred years.^[16] Any input of OM to soils can increase the subsoil SOC pool when it is stabilized and not completely mineralized to CO₂.^[17] Charring of OM creates biochemically recalcitrant black carbon which may be stabilized preferentially at deeper soil depths.^[18] At lower soil depths, decomposed plant material may directly interact with metal oxides resulting in OM stabilization, whereas in deep mineral soil, OM could mainly interact with metal oxides after microbial turnover.^[19] In subsoil horizons, easily available polysaccharides and nitrogen-rich microbial material

may be stabilized by interactions with the mineral phase but not lignin.

QUANTITY OF SUBSOIL OC

Routine soil surveys are restricted to about 1 m depth with exploring greater depths of profile development, and measurements of SOC stocks below 1 m depth are rare.^[20] Estimates for the vertical distribution of SOC are highly uncertain (Table 2). The reliability of estimates of SOC storage is affected by unreliable *in situ* measurements of SOC, soil depth, and bulk density.^[23] Variability in the estimates of global SOC distribution is due to variation in the definitions of soil units, differences in soil property databases, scarcity of information about SOC at depths >1 m in peatlands, and variation in the definitions of “peatland.”^[22] Given the limitations, 39–70% of the total SOC in the upper 1 m are stored in the first 30 cm.^[21] The global SOC stock increases by 30–60% when the second meter of soil is included and by additional 18% when the third meter is included.^[11,21] About 56% of the total profile SOC stock without depth limit is found below 1 m depth.^[22]

In particular, the root OM may be translocated below 1 m depth as is indicated by the maximum rooting depths for grasses, shrubs, and trees (Table 1) and by the global average maximum rooting depth of 4.6 m.^[12] The root densities, however, are highest in the upper 20 cm of the soil profiles.^[24] It is estimated that soils in permafrost regions store globally more SOC below 1 m than up to 1 m depth (i.e., 1176 Pg C vs. 496 Pg C).^[25] Further, peatlands may contain about 6% of the tropical SOC mass within the first meter (22.0 Pg C) and approximately 21% of the total tropical SOC mass (88.6 Pg C; without depth limit).^[26] Estimated totals of SOC stock for the second and third meters indicate that globally tropical evergreen forests, grasslands, and savannas store most SOC between 1 and 3 m depth.^[11]

The SOC stocks in the upper meter of the most soil profiles drop off quickly, but stocks in underlying horizons are not negligible (Table 1). Especially where deep soils (profiles greater than 5 m deep) coincide with deep rooting, the biological deposition of C from roots and their associated biota is inevitable at great soil depths; e.g., soils from sites in the deeply weathered regolith in Australia contained 59% of the total SOC store to bedrock (mean depth 21 m) in the surface 5 m.^[27]

Table 2 Global estimates of the vertical distribution of SOC.

Depth (m)	Total SOC storage (10 ¹⁵ g C) estimated by		
	Batjes ^[21]	Köchy et al. ^[22]	Jobbágy and Jackson ^[11]
0–0.3	684–724		
0–1	1462–1548	1325	1342–1662
0–2	2376–2456		1758–2228
0–3			2104–2584
Without depth limit		3000	

SUBSOIL OC TURNOVER TIMES

Environmental conditions are important for regulating SOC turnover times.^[28] The slow turnover times and old radiocarbon ages of SOC in deep soils may be the result of 1) depressed microbial biomass and activity due to low rates of oxygen diffusivity, low soil moisture, and nutrient availability; 2) the microbial recycling of aged C compounds; and 3) aging during the slow, downward migration of C that escapes mineralization from upper soil horizons.^[2] Incorporation of OC into soil aggregates and associations with mineral surfaces, cations, or metals also contribute to slow turnover times of SOC at depth. However, deep SOC may be more dynamic as previously thought and may play a role in the contemporary C cycle. Specifically, the ¹⁴C age of SOM fractions is not necessarily related to molecular structure or thermodynamic stability.^[29] For example, modern ¹⁴C is incorporated into subsurface soils, and ancient SOC can respond to disturbances on annual to decadal timescales.^[30,31]

CONCLUSION

Studies on the vertical distribution of SOC below 1 m depth are rare. The subsoil may, however, receive appreciable amounts of OM as DOC with the percolating water, because of bioturbation by soil animals, by soil microorganisms, and by soil burial but probably most notably by root litter and rhizodeposition. As the turnover time of SOM increase with depth, the subsoil has the potential of C sequestration. Future work must focus on understanding the dynamics of deep SOC depending on land use and climate changes and how the subsoil OC stock can be enhanced. Soil ecosystem services will also benefit from higher amounts of subsoil SOC as, e.g., the subsoil contributes to plant nutrition.

Organic Farming: China

Yuxin Miao

Fusuo Zhang

Fanghao Wang

College of Resources and Environmental Sciences, China Agricultural University, Beijing, China

Abstract

Although Chinese farmers have practiced traditional organic farming for over 4000 years, China's organic farming history started only in 1990 and has witnessed fast developments since 2000. This entry introduces the history, status and challenges, and future prospects of organic farming in China, as well as other eco-labeled foods (pollution-free and green foods).

INTRODUCTION

China has been internationally acclaimed during the past few decades for achieving food security for the largest population in the world and that too with a limited cropland area. However, this success was achieved at the cost of high external inputs, low resource use efficiencies, serious ecological and environmental problems, and increasing food safety concerns. To address the problems associated with conventional agriculture, China has explored different alternative practices, especially those requiring less external chemical inputs. As a result, the development of ecological agriculture, organic farming, and eco-labeled foods (pollution-free, green, and organic foods) have received increasing attention. This new development of organic farming complies with international organic farming standards and has only a short history in China. This entry introduces the definition, history, status, challenges, and future prospects of organic farming in China.

DEFINITION

Although there are many definitions, organic farming in this entry refers to agricultural management systems that are based on ecological and sustainable development principles and agronomic, biological, manual, or mechanical methods without using synthetic chemical fertilizers, pesticides, growth regulators, livestock feed additives, or genetically modified organisms during the production process and are internationally certifiable (with controls and traceability).^[1,2]

HISTORY OF ORGANIC FARMING IN CHINA

China has a long history of traditional organic farming. For over 4000 years, Chinese farmers used strategies of crop

rotation and diversification, intercropping, thorough tillage, terracing, various sources of organic manure (e.g., animal waste, human excreta, cooking ash, compost, and dredged sediments), nitrogen (N)-fixing green manures, and manual methods to produce food, maintain soil fertility, and control pests.^[3,4] Increase in population and urgency to achieve food security led to a replacement of this natural, subsistence-oriented traditional organic farming by conventional (or intensive) agriculture. This transition started during the middle of the 20th century and was based on the Green Revolution technologies to maximize agricultural output. The rich experience of millennia in traditional farming, however, formed a good foundation for the development of China's organic farming systems.

To address the problems of conventional agriculture, China started ecological agriculture in the beginning of the 1980s, which has specific limitations with regard to inputs of agrochemicals. By the mid-1990s, China had established about 1200 demonstration eco-villages and farms,^[2] which was the first step toward the development of organic farming in China. China started the Green Food program in 1990.

The Green Food is produced and processed with controlled and reduced use of synthetic inputs and domestically certified and labeled to be safe from chemical contamination.^[1,5] It is administered by China Green Food Development Center under the Ministry of Agriculture (MOA), which was established in 1992. Green Food production has seen steady increase since its start, due to reduced chemical input costs without productivity reduction and 10–50% price premium.^[5] The Green Food program has paved the way for China's organic farming development since 2000.

Also in 1990, China's Organic Green Tea from Lin'an County of Zhejiang Province was certified by the Dutch certifier SKAL and exported to the Netherlands, setting the milestone of organic farming in China. Nanjing Scientific

Research Institute's Rural Ecology Research Lab, under National Bureau of Environmental Protection (NBEP), joined International Federation of Organic Agriculture Movement (IFOAM) as China's first IFOAM member in 1989. This developed into Organic Food Development Center (OFDC) of NBEP in 1994 and later was renamed as OFDC of State Environmental Protection Administration (SEPA). The OFDC was finally given full accreditation by IFOAM in 2003, and Chinese organic products certified by OFDC can be sold as organic food around the world.^[2] During the same year, the administration of China's organic products certification was taken over from SEPA by Certification and Accreditation Administration of China (CNCA).

The year 2005 was an important year for China's organic farming development. The General Administration of Quality Supervision, Inspection and Quarantine issued the "Regulatory Measures on Organic Product Certification Management" and National Standard for Organic Products (GB/T 1963–2005). This standard includes the following four components: production, processing, logo, and marketing and management system.^[2] The CNCA published "Implementation Rules for Organic Product Certification," and a standard national logo for organic products was introduced.

China has seen the fastest organic farming development in the world, moving from 45th in 2000 in terms of hectares under organic management to 16th in 2005, and then to the 2nd position in 2006, accounting for 11% of world's total organic area.^[6] This rapid development was facilitated by the Green Food program, which acted as a stepping-stone for the farmers to move from conventional chemical farming to modern organic farming. Green Food started as a local standard and later was differentiated into Grade A and Grade AA. Grade AA is very close to organic food, prohibiting the use of any chemicals in the production process. It will be phased out gradually and merged with the international organic standard.^[1,6,7] A key difference between Green Food and organic certifications is that Green Food certifies both production and outcome, while organic certification certifies only the production process.

EXISTING STATUS

According to CNCA, the area under organic farming management was only 34.26×10^4 ha by the end of 2003 and increased to 97.8×10^4 ha (not including aquaculture, wild production, and poultry and livestock production) in 2005.^[2] In 2006, certified organic farm land area and production were 2.1 million ha (Mha) and 2.80 million tons, respectively, making China as the 3rd largest country in terms of area after Australia (11.8 Mha) and Argentina (3.9 Mha), according to the China Organic Food Certification Center (COFCC), as cited by Scoones.^[8] There was more than 2 Mha of wild collection (with 0.05 million ton

production) and additional 1.1 Mha in conversion (with 1 million ton production).^[8] If these were all added up, China would rank as the 2nd country in the world.

The main certified farm lands are located in Northeast China (Liaoning, Jilin, and Heilongjiang provinces) for grain and soybean production, East China (Shandong, Jiangsu, and Zhejiang provinces) for vegetable production, and South China (e.g., Zhejiang, Jiangxi, and Yunnan provinces) mainly for organic tea production. The processing companies are mainly distributed in developed areas of the east (i.e., Shanghai, Beijing, Zhejiang, Shandong, and Jiangsu provinces).^[9]

China's organic products are mainly export driven and oriented, especially during the early development stage. Before 1999, over 95% of organic products were exported to Japan (mainly vegetables and some field crops like rice and soybeans), the European Union (organic tea and field crops), and North America.^[8] According to COFCC, the value of exported organic products increased from US\$0.3 million in 1995 to US\$0.35 billion at the end of 2004, which accounted for 1.7% of total Chinese agricultural export and 1.2% of global trade in organic products. Domestic organic market started from 2000 and is concentrated mainly in some large cities, with a retail value of US\$750 million in 2006 (COFCC, as cited by Scoones).^[8] The price of conversion to organic vegetables was reported to be 3 to 5 times that of the conventional vegetables in Beijing and Shanghai, yet only 1.5 to 3.0 times in other cities such as Nanjing.^[2]

In addition to organic and green food, pollution-free food is another eco-labeled food, which was launched in 2002 and certified by the Center for Agri-Food Quality and Safety under MOA. This is a Chinese standard to address basic food safety issues and thus has lower standards compared with green and organic foods. Pollution-free food label is only in Chinese, while labels of the other two types of certified foods are in both Chinese and English, including conversion to organic food (Fig. 1). In 2007, there was a total of 34.18 Mha eco-labeled foods in China, with 21.07, 10, and 3.11 Mha for pollution-free, green, and organic food, respectively.^[7]

Organic food production in China is organized in the following three main models: 1) company owns organic production base; 2) company rents land from farmers for long term, and farmers are employees of the company; and

Fig. 1 Labels denote the types of food producers: (A) pollution-free food, (B) green food, (C) organic food, and (D) conversion to organic food.

3) “Company plus Farmers” model, which is the most widely adopted one based on contracts signed between a company and farmers. The farmers grow organic products in their own fields under the company’s guidelines, and the company purchases their products.^[9] One effective management method to ensure that the farmers will follow the guidelines is to group local contract farmers together for collective responsibility, and if one farmer has violations, none of the products from the group is purchased by the company.^[8]

CHALLENGES AND FUTURE PROSPECTS

Organic farming is at its early stages in China and lacks sufficient research, technology, and policy support. Organic farming is knowledge intensive and has higher requirements from the producers. However, many organic farming technologies are not mature in China, and most Chinese farmers have much less education and training than those in developed countries. Most young farmers with good education generally seek off-farm jobs. Thus, developing a good research, extension, and training system for organic farming technologies is crucially important and urgently needed. Crop yields are generally low during the initial conversion period, and it requires more financial and labor investment. Thus, farmers take some financial risks and need policy support. Ensuring organic farming production standards and marketing can also be challenging with scattered and small-scale production.

Achieving food security is the top priority in China. To meet the food demand of the increasing population, China needs to continue to increase crop yields. Crop yield in organic farming is generally lower than that in conventional intensive farming, and it requires rotation with leguminous crops or N-fixing green manures once every 2 or 3 years (or 1/3–1/2 of crop land each year) to maintain soil fertility. Therefore, organic farming is not likely to become the mainstream farming in China in the near future. Pollution-free and green food production systems, on the one hand, may become more widely accepted in China, as they can meet the food safety demand without sacrificing

crop yields. Organic farming, on the other hand, may gain more development in production systems with more emphasis on product quality rather than high agronomic yields.

Abstract

Organic fertilizers affect the heavy metal balance of agroecosystems by supply, mobilization, and immobilization. Supply and mobilization are useful options in terms of feeding plants with essential heavy metals but are a risk for loading sensitive environments. Immobilization in and removal from soil of heavy metals by phytoremediation are deceptive options: The former leaves the risk in place, while the latter is too inefficient in terms of masses removed and just shifts the problem of contamination to other ecological compartments. The only feasible option for protecting soils, food, and environment is applying the precautionary principle by balancing all sources of input and output of heavy metals to an ecosystem.

INTRODUCTION

Heavy metals are elements with atomic weights ranging between 63.54 [copper (Cu)] and 200.59 [mercury (Hg)] and specific gravity greater than 4.0 g/cm³. Some elements may stimulate growth of an organism, although the evidence for this process is lacking. Micronutrients important to plant growth are Cu, cobalt, manganese (Mn), iron, zinc (Zn), and molybdenum (Mo). Other trace elements do not play any physiological function and are toxic in extremely small quantities.^[1,2] There is a strong link between micronutrient nutrition, the uptake, and the impact of contaminants of plants, animals, and humans.

Contamination with heavy metals has become one of the most serious problems for the functionality of ecosystems. Because of the industrial development and past disposal activities, heavy metals are considered to be among the most important environmental contaminants that affect terrestrial, aquatic, and atmospheric systems. Concerns about these contaminants are based on the fact that certain trace elements [e.g., arsenic, cadmium (Cd), lead (Pb), or uranium (U)] are accumulating in the food chain threatening the health of humans and animals.^[3] The risks of human, crop, and/or environmental toxicity posed by these elements are a function of their mobility and availability in soil.^[4] The concentration of heavy metals in the soil solution, as the main parameter for the bioavailability of heavy metals to plants, is affected by numerous factors. Among others, the uptake of heavy metals by plants from soils is also affected by management factors like organic fertilization. Despite the fact that organic fertilizers themselves can

be a source for heavy metals, nevertheless organic matter (OM) added with manures, compost, and sludges greatly increases soil physical features like colloidal stability and cation exchange capacity and chemical features like plant available nutrients and chelating compounds which have a beneficial effect on soil biology.

Organic fertilization may affect the transfer of heavy metals to plants by several mechanisms: enhancing metal adsorption as a result of increased surface charge and increasing the formation of organic complexes including changes of the redox potential in soils toward negative values. It may additionally not only increase the solubility of some elements like Mn but also decrease the solubility of other elements like U.^[5] The oxidation of OM releases protons and lowers the pH of the soil which increases Mn and Zn solution concentration or lowers the mobility of Mo.^[6] A higher cation exchange capacity and increased concentrations of chelating agents, because of the organic fertilization, improve soil's storage capacity for heavy metals. This function acts as a buffer system against heavy metal transfers in ecosystems, either by preventing them from leaching or by counteracting their accumulation in food plants.^[7] Metal retention processes are generally much more important than metal leaching processes.

SOURCES OF ORGANIC FERTILIZERS

Differences between organic fertilizers must also be considered. Some typical metal concentrations in organic fertilizers are given in Table 1. Narwal and Singh^[8] observed

Table 1 Typical heavy metal concentrations in selected organic fertilizers.

Organic fertilizers	Zn (mg/kg dry weight, range)	Cd (mg/kg dry weight, range)	Cu (mg/kg dry weight, range)	Ni (mg/kg dry weight, range)	Pb (mg/kg dry weight, range)	References
Manure						
Pig	206–716	0.19–0.53	160–780	3–24.3	1.01–4.65	[9,10]
Cattle	41–238	0.15–0.40	26.2–55.8	1.7–9.1	1.5–8.4	[10]
Poultry	350–632	0.44–2.04	49.4–74.8	4.5–11.4	3.36–14.8	[10]
Slurry						
Pig	639–2115	0.32–1.08	197–773	8.6–11.6	2.7–7.0	[11,12]
Cattle	68–235	0.11–0.53	17.5–48.7	1.9–20.4	4.1–8.4	[10,13]
Sewage sludge	700–50,000	2–1,500	50–3,300	16–5,300	50–3,000	[9]
Green compost	72–181	0.11–1.7	17–432	5.7–25	15–131	[14]
Biowaste compost	125–371	0.11–0.7	34–215	7.2–37.7	19–435	[15]

that increasing rates of cow and pig manure decreased the amounts of extractable Cd and nickel (Ni), whereas the addition of peat, at the same rate of as OM, had an increasing effect. At this point, the effects are linked to farming systems, which affect, either directly or indirectly, the quantities of compounds of plant or animal origin introduced into the soil.^[16]

All factors involved in the effects of OM with heavy metal mobility show distinct interaction, like pH and the formation of metal-organic complexes. Most metals (in free ionic form) have a higher mobility in acidic, coarse-textured soils,^[17] but mobility, however, can be also significant at about neutral or higher pH owing to the fact that dissolved OM becomes itself more soluble at those pH levels and because of the formation of soluble organometallic complexes. That is why the release of Cd into the soil solution as metal-organic complex becomes significant when the soil pH exceeds 5.5,^[4,18] and Pb leaching increases with a higher concentration of dissolved OM and pH.^[19] Such interactions are of great importance when the remediation of heavy metal polluted soils is discussed. In terms of preventing heavy metals from transferring to ecosystems, the aim of remediation is not decontamination but immobilization through increasing the binding capacity of the soil.^[20]

The largest sources for OM in agricultural systems are plant residues. Gupta et al.^[21] observed a considerably higher content of Cd in wheat grown after the addition of pulses than when the same crop was grown after cereals. This may indicate an effect of nitrogen applied with the organic fertilizers by a synergistic effect of the former on heavy metal uptake, which has been described by Schnug.^[22]

In the point of view of negative anthropogenic activities on soil quality, the loss of OM is a particularly serious problem, which also diminishes the buffer capacity of soils for heavy metals. The utilization of wastes, as soil amendments to counteract losses of OM,^[23,24] is only an apparent and short-sighted solution because these sources are usually highly polluted with heavy metals (Table 1).

PLANT UPTAKE OF HEAVY METALS

Typical heavy metal concentrations in not accumulating higher plants are (mg kg^{-1}) as follows: Cd, 0.1–1; Cu, 3–15; Hg, 0.1–0.5; Ni, 0.1–5; Pb, 1–5; and Zn, 15–150.^[23] There are numerous evidences of an increase in heavy metal phytoavailability and crop uptake related to the land application of sewage sludge, fly ash, poultry litter, pig slurry, and other biosolids.^[25–27] Supplementing swine feed with Cu has been a common practice for many years, and just environmental concerns have been expressed over elevated Cu concentration in soils receiving the long-term application of swine waste. On such sites, Cu is preferentially adsorbed by OM associated with the coarse fraction in soil.^[28] Sludge-derived OM contributes significantly to the metal adsorption capacity, and the slow mineralization of this OM can release metals into more soluble forms.^[29] Because the decomposition of sludge OM is often associated with the acidification of soil, further increased bioavailability of the sludge-born heavy metals is to be considered^[30] resulting in enhanced availability of heavy metals, decades after sludge application.^[31] Wastes with unsuitable agronomic features can be processed to suitable fertilizers by a variety of methods such as drying, composting, alkaline stabilizing, or incineration to reduce sludge mass, volume, concentration, and mobility of metals.^[4]

Any use of organic amendments must consider possible effects on heavy metal availability, especially when the initial contamination of a soil is already high. Under these circumstances, even the use of composts with low metal concentrations can be questionable because of the mobilization action of soluble organic compounds.^[32]

CONCLUSION

Organic fertilizers affect the heavy metal balance of agroecosystems by supply, mobilization, and immobilization. Supply and mobilization are useful options in terms of

feeding plants with essential heavy metals (e.g., Zn and Cu) but are a risk for loading sensitive environments. Immobilization in and removal from soil of heavy metals by phytoremediation [increased uptake by accumulating plant species (e.g., *Polygonum spec.*)] are deceptive options: The former leaves the risk in place, while the latter is too inefficient in terms of masses removed and just shifts the problem of contamination to other ecological compartments. The only feasible option for protecting soils, food, and environment is applying the precautionary principle by balancing all sources of input and output of heavy metals to an ecosystem.

Organisms and Soil Food Webs

David C. Coleman

Institute of Ecology, University of Georgia, Athens, Georgia, U.S.A.

Abstract

Soils may be viewed as the organizing centers for terrestrial ecosystems. This is largely the result of organismal activities in the soil. Major functions such as ecosystem production, respiration, and nutrient recycling are controlled by the rates at which nutrients are released by decomposition in the soil and litter horizons. The array of biota, including microbes, microbe-feeding fauna, vegetation, and consumers are all influenced by soil processes, and the organisms in turn have an impact on the soil system.

INTRODUCTION

Soils provide a wide range and variety of microhabitats, thus accommodating a very diverse biota. The enormous surface area (hundreds of m²/g of soil) of soil particles ranges in size classes from clays (0.1–2 µm in diameter) to silts (2–50 µm in diameter) and sands (0.05–2 mm in diameter). Numerous microbes and micro- and mesofauna (protozoa and nematodes) exist in water films on these particles and in or on the surfaces of microaggregates formed from the primary particles.^[1] In turn, the more mobile fauna, from collembola and mites (larger mesofauna) to the macrofauna (earthworms, millipedes, ants, termites, and fossorial or earth-dwelling vertebrates) move through macro- and micropores in the soil. The macrofauna play a role in moving parts of the soil profile around and form many sorts of burrows and pores, and they are often termed “ecological engineers.”

SOIL FOOD WEBS

The initial breaking up or “comminution” of plant litter (above- and below-ground) results from the chewing and macerating action of both large and small animals. This comminution benefits the fauna, which derive nutritional benefit from the litter and/or microbes initially colonizing the plant material. The increased surface area and further inoculation of the smaller pieces enhance the microbial access to, and breakdown of, these tissues. The decomposition process drives complex food webs^[2,3] in the soil, with numerous interactions between the initial agents of decomposition, the bacteria and fungi, and the fauna that in turn feed upon them, which facilitates nutrient return in the soil matrix (Fig. 1). These feeding relationships have several trophic levels, with bacteria and fungi being fed upon by microbe feeders, such as protozoa, nematodes, and microarthropods, which are in turn preyed upon by predatory nematodes or mites, and these in turn fed upon

by higher predators (Fig. 1). In forests or no tillage agroecosystems, where fungi dominate in the surface litter, the dominant flows of energy and nutrients will go via fungal pathways. In contrast, in conventional tilled fields where the organic matter is incorporated in the plow layer (usually 6–8 in. = 15–20 cm), the dominant flows of energy and nutrients may be more bacterially dominated, usually decomposing faster than in the no tillage system.^[1]

ZONES OF INFLUENCE

The heterogeneous distribution of food resources in the soil matrix makes it difficult to sample adequately for abundances and activities of the biota in a repeatable fashion. A useful approach is to consider soils as being comprised of zones of influence (ZOI) that can be targeted for further study. These ZOI, also termed “hot spots,” are located in the root rhizosphere, in regions of organic detritus accumulation, or detritusphere, and also in earthworm-influenced regions, such as burrows, which are termed a drilosphere^[4] (Fig. 2). These ZOI may represent less than 10% of the volume of the surface A horizon but account for up to 90% of the total biological activity in soils worldwide.

ROLES OF BIOTA IN SOIL FOOD WEBS

The functional roles of soil organisms can be compared most usefully in terms of body width. The microbes and microfauna inhabit soil water films and are restricted to this aquatic milieu. In contrast, the meso- and macrofauna, from acari (mites) to earthworms, inhabit gas-filled pores and move around in the soil matrix for considerable distances (Fig. 3).^[5]

Bacteria

Bacteria are unicellular prokaryotes (organisms lacking a unit membrane-bounded nucleus and other organelles),

Fig. 1 Representation of detrital food web in shortgrass prairie. Fungal-feeding mites are separated into two groups (I and II) to distinguish the slow-growing oribatids from faster-growing taxa. Flows omitted from the figure for the sake of clarity include transfers from every organism to the substrate pools (death) and transfers from every animal to the substrate pools (defecation) and to inorganic N (ammonification).

Source: From Hunt, Coleman, et al.^[2]

which are found in all habitats on earth. They are exceedingly numerous (more than 10^{30} or one million trillion trillion^[6]) and diverse, comprising over 35 kingdoms in two domains, the Archaea and Eubacteria. They are active in all aspects of elemental cycling, and needed for nitrogen (N) cycling, both in N fixation (splitting N_2 and incorporating N into organic compounds) and subsequent transformational pathways as well. They are also primary agents of decomposition in many habitats and are particularly active in rhizospheres.^[4]

Fungi

Fungi are multicellular eukaryotes that are found in many habitats worldwide. They have long, ramifying strands (hyphae) which can grow into and explore many microhabitats and are used for obtaining water and nutrients. The hyphae secrete a considerable array of enzymes, such as cellulases, and even lignases in some specialized forms (useful in breaking down wood), decomposing substrates *in situ*, taking up the decomposed subunits, and

translocating them back through the hyphal network. Fungi are very abundant, particularly in undisturbed forest floors, in which literally thousands of kilometers of hyphal filaments will occur per gram of leaf litter.

The roles of mycorrhizas (literally “fungus–root,” or symbiotic fungi associated with many plants) in soil systems are being increasingly viewed as central to much of terrestrial ecosystem function. Mycorrhizas are essential to the growth and reproduction of numerous families of plants.^[1]

Microfauna

The unicellular eukaryotes, or Protoctista, are more often called protozoans. They include the flagellates, naked amoebae, testacea, and ciliates. These organisms range in size from a few cubic micrometers in volume (micro flagellates) to larger ciliates, which may be up to 500 μm in length and 20–30 μm in width. Protozoa are abundant, reaching densities of from 100 to 200 thousand per gram of soil. Bacteria, their principal prey, often exist in numbers up to one billion per gram of soil. All of these organisms are

Fig. 2 Areas of activity in soil systems. These “ZOI” may be <10% of the total soil volume but represent >90% of the total biological activity in most soils worldwide.

Source: From Beare, Coleman, et al.^[4]

true water-film dwellers and become dormant or inactive during episodes of drying in the soil. They can exist in inactive or resting stages literally for decades at a time in very xeric environments.

Mesofauna

Nematodes

Nematodes have a wide range of feeding preferences. A general trophic grouping is bacterial feeders, fungal feeders, plant feeders, and predators and omnivores. Anterior (stomal or mouth) structures can be used to differentiate general feeding or trophic groups. Because nematodes reflect the developmental stages of the systems in which they occur (e.g., annual vs. perennial crops, or old fields and pastures and more mature forests), they have been used as indicators of overall ecosystem condition.^[7,8]

Collembola

Collembolans, or “springtails,” are primitive apterygote (wingless) insects. They are called “springtails” because

many of them have a spring-like lever, or furcula, which enables them to move many body lengths away from predators in a springing fashion. Collembolans are ubiquitous members of the soil fauna, often reaching abundances on 100,000 or more per m². They occur throughout the soil profile, where their major diet is decaying vegetation and associated microbes (usually fungi). However, like many members of the soil fauna, collembolans defy placement in exact trophic groups. Many collembolan species will eat nematodes when those are abundant. Some feed on live plants or their roots. One family (Onychiuridae) may feed in the rhizosphere and consume mycorrhizas or even plant pathogenic fungi.^[9]

Mites (Acari)

The soil mites, Acari, are chelicerate arthropods related to the spiders. They are often the most abundant microarthropods in soils. A 100 g sample may contain as many as 500 mites representing nearly 100 genera. This diverse array includes participants in three or more trophic levels, with varied strategies for feeding, reproduction, and dispersal.

Fig. 3 Size classification of organisms in decomposer food webs by body width.

Source: From Swift, Heal, et al.^[5]

The oribatid mites (Oribatei) are the characteristic mites of the soil and are usually fungivorous or detritivorous. Mesostigmatid mites are nearly all predators on other small fauna, although a few species are fungivores and may become numerous at times. Astigmatid mites are associated with rich, decomposing N sources and are rare except in agricultural soils. The Prostigmata contains a broad diversity of mites with several feeding habits.^[1]

Macrofauna

Termites (Isoptera) are one of the major ecosystem “engineers,” particularly in tropical regions. Termites are social insects with a well-developed caste system. By their ability to digest wood, they have become economic pests of major importance in some regions of the world. The termites in a primitive family, the Kalotermitidae, possess a gut flora of protozoans, which enables them to digest cellulose. Their normal food is wood that has come into contact with soil. Many species of termites construct runways of soil, or along root channels, and some are builders of large, spectacular mounds. Members of the phylogenetically advanced family Termitidae possess a formidable

array of microbial symbionts (bacteria and fungi but not protozoa), and elevated pH in their hindguts,^[10] which enable them to process and digest the humified organic matter in tropical soils and to thrive on it.

Termites parallel earthworms in ingestive and soil turnover functions. The principal difference is that earthworms egest much of what they ingest in altered form (that enriches microbial action), whereas termites transfer large amounts of soil (organic material into building nests and mounds (carbon sinks).

Earthworms

Much of the evidence for earthworm effects on soil processes comes from agroecosystems and involves a small group of European lumbricids (Lumbricidae family in the Oligochaeta order). Impacts of exotic earthworms on native species are not well understood, although there is evidence that when native habitat is destroyed and native earthworm species extirpated, exotic earthworms colonize the newly empty habitat. As more extensive studies are carried out, it is becoming clear that earthworms are present in a wide variety of tropical as well as temperate ecosystems.

Earthworms have important roles in the fragmentation, breakdown, and incorporation of soil organic matter (SOM). This affects the distribution of SOM and also its chemical and physical characteristics. Changes in any of these soil parameters may have significant effects on other soil biota, by changing their resource base (e.g., distribution and quality of SOM, microbes, or microarthropods) or by changing the physical structure of the soil.^[11] Earthworm activities impact the communities of other soil biota through their effects on the chemical and physical characteristics of SOM, causing changes in the microbial and microarthropod communities, and also having impacts elsewhere in the soil food web.^[12]

CONCLUSION

Soil biota are very interconnected with each other by a variety of trophic and nutrient-flow pathways. The possibility of enhancing biotic activity in agricultural systems via conservation or no tillage regimes is very great, and much research is focusing on this area of interest. This approach permits a melding of interests between those who want to reduce fossil fuel inputs to agroecosystems and those who are concerned with enhancing carbon sequestration in soils as well.

Abstract

Organo-mineral relationships are a fundamental feature of soils and are often used to define and differentiate soils from geological parent materials. Soil is primarily a mineral matrix (except in organic soils such as bog peat) but receives inputs of organic materials from various natural sources such as litterfall, root exudates, or from various anthropogenic sources such as manure additions. Organo-mineral relationships range in degree of association from the spatial distribution of particulate organic matter and mineral particles with minimal interaction to the inseparable organic matter intercalated between clay layers. Here, the term association is used to describe an arrangement of organic matter and minerals that has an undefined degree of cohesion. The term complex is restricted to cases where adsorption is the dominant mechanism.

INTRODUCTION

Organo-mineral associations cover a wide range of spatial scales, from nanometric (e.g., the complex of an organic acid with a clay sheet) to decimetric (e.g., a soil ped); however, they all originate at the molecular scale where physico-chemical interactions lead to the formation of bonds. The formation of organo-mineral associations may require only minutes, but their lifetime is related to that of the organic component, which can be short or extend to thousands of years. The impact of organo-mineral complexes in soils is significant; 40–80% of soil carbon is present in clay-sized separates and cannot be separated easily from clay minerals.^[1] Their importance is also qualitative and functional because the formation of organo-mineral complexes in soils strongly impacts the properties of the mineral phase and influences the biodegradation of organic matter.

CHARACTERIZATION OF ORGANO-MINERAL RELATIONSHIPS

Historically, organic matter has been studied by methods that involved their solubilization and separation from soil minerals. On the other hand, mineralogists analyzed soil minerals after comprehensive destruction of organic matter with hydrogen peroxide. Therefore, most of the knowledge concerning organo-mineral associations was gained from

studies performed on synthetic organo-mineral complexes, prepared from well-defined constituents such as clay minerals from geological deposits and pure organic compounds (e.g., polysaccharides and proteins).^[2] Physical methods for soil fractionation such as size or density separation enable the separation of intact organo-mineral associations from soils and their direct study with a wide range of non-destructive methods such as nuclear magnetic resonance spectroscopy.^[3]

Primary organo-mineral associations are associations of organic matter with individual soil mineral particles.^[4]

Their separation requires complete dispersion of soil using mechanical means and size or density separation techniques. Secondary organo-mineral associations, namely aggregates, are made by grouping together of several primary organo-mineral associations. Secondary organo-mineral associations are normally isolated from soil by sieving techniques after mild soil dispersion (e.g., a simple immersion of soil sample in water and agitation).^[5]

In primary organo-mineral associations, more organic matter is more closely associated with minerals as particle size decreases: sand-sized organic matter (i.e., decomposing plant debris) is separated easily from sand-sized minerals by densimetric techniques,^[6,7] whereas little free mineral or organic matter seems to occur in the clay-sized fraction.^[8] A variety of compounds are involved in primary organo-mineral associations. The clay-sized associations consist of highly processed and humified compounds, as

well as microorganisms and their metabolites.^[1,4,9] Clay-organic matter associations also show diverse microstructures, from organic interlayer complexes^[10,11] and organic coatings on clay mineral surfaces to more complex structures such as microaggregates of bacteria or plant debris with clay particles^[12,13] (Fig. 1).

In various soil types and management contexts, secondary organo-mineral complexes are hierarchical: particles associate into microaggregates, which in turn associate into larger aggregates.^[15–18] The smaller the aggregate hierarchical level, the higher is its physical stability, because the binding agents involved change with the spatial scale. Clay-sized associations are bound by sesquioxides, humic materials, and polysaccharides. These associations are bound into <250 μm microaggregates by bacterial and fungal debris, which may further be bound into macroaggregates >250 μm by transient agents (e.g., polysaccharides) and temporary ones (e.g., fine roots and fungal hyphae; Fig. 2).^[19,20] Aggregates appear

to be formed and stabilized around decomposing plant debris that act as hot spots for microbial activity^[17,21–24] (Fig. 3).

Binding Forces within Organo-Mineral Associations

A variety of bonds may be formed when organic molecules in solution come into contact with the surface of soil minerals (see Fig. 4).^[26] For small organic molecules, these interactions depend on their ability to establish electrostatic interactions or dipole interactions. Polarity and polarizability are thus important adsorption-related properties of such organic molecules. For macromolecules, weak interactions such as van der Waals interactions and hydrogen bonding become very important. The conformation of macromolecules largely influences their adsorption, which increases with molecular weight.^[2] High-molecular-weight polymers are generally adsorbed in an irreversible fashion and

Fig. 3 Schematic presentation of the interaction between soil organic matter decomposition and aggregate formation and destruction.

Source: Adapted from Golchin, Oades, et al.,^[22] Chenu, Puget, et al.,^[23] Balesdent, Chenu, et al.^[25]

therefore the adsorption of macromolecules into soil minerals often leads to the formation of stable organo-mineral complexes. Organic polymers such as polysaccharides, proteins, fulvic, and humic acids are active in the formation of organo-mineral complexes because of their high molecular weight and charge. Similarly, clay minerals are the most active mineral constituents in the formation of organo-mineral complexes because of their charge and their high specific surface area.^[2] Solid particles such as bacteria, fungi, or plant debris also establish physico-chemical interactions with mineral surfaces through the process of adhesion.

Physico-chemical interactions at the molecular scale (i.e., adsorption and adhesion) provide tensile forces that increase both the tensile strength and the compressive strength of primary as well as secondary organo-mineral complexes and associations.^[27–29] At a larger scale, the binding of aggregates also involves physical mechanisms.

Fungal hyphae and fine roots stabilize aggregates by entangling the soil particles^[30–32] and thereby increasing aggregate strength through compressive forces. Physical processes such as those related to shrink–swell or freeze–thaw also alter organo-mineral associations by 1) creating failure zones that separate aggregates^[15,33] or 2) increasing the contacts between the organic and mineral surfaces and thus aiding the creation of new bonds.^[34,35]

ORGANO-MINERAL RELATIONSHIPS ALTER THE PROPERTIES OF SOIL MINERALS

Soil properties observed at a macroscopic scale are largely due to changes in the properties and associations of soil primary particles at a microscopic scale, in particular that of clay minerals. For example, the basic physical and physico-chemical mechanisms by which organic matter stabilizes soil aggregates against the disruptive action of water are an increased cohesion of the aggregate or a decreased wettability. Increased cohesion helps the aggregate withstand mechanical disruption by raindrops and resist forces exerted by compressed air upon wetting. Adsorption of large and flexible organic polymers increases the tensile strength of minerals (see above). Decreased wettability of aggregate surfaces slows the rate of wetting of the aggregates and thus the extent of slaking. Synthetic complexes of clays and humic substances, as well as natural complexes, are less wettable than pure clays.^[36–38] Associated organic matter also changes the swelling of clays and organo-mineral associations.^[39–41]

Organo-mineral associations alter the reactivity of soil minerals, particularly of soil clays, thereby altering the retention of cations, trace metals, or organic pollutants in soils. Associated organic matter increases the cation-exchange capacity of soils and soil clays,^[42–44] which contributes to the preferential retention of heavy metals by clay-sized fractions of soils. Increased hydrophobicity in

Fig. 4 Mechanisms of interaction between clay minerals and organic molecules.

the clay fraction, caused by associated organic matter, facilitates the sorption of non-polar organic pollutants.^[46]

ORGANO-MINERAL RELATIONSHIPS REDUCE THE BIODEGRADATION RATE OF ORGANIC MATTER

Many easily decomposed compounds are retained in soil for longer periods than expected from their biochemistry. Association of organic matter with soil mineral particles and aggregates usually results in a decrease in the rate of biodegradation of the organic matter. Bartlett and Doner^[47] measured the decomposition of two radiolabeled-amino acids in four treatments: in a non-aggregated and non-adsorbed state; in a non-aggregated but adsorbed state; in an aggregated but non-adsorbed state; and in an aggregated and adsorbed state. The results showed that decomposition was more rapid in the non-aggregated vs. aggregated state, and that adsorption further decreased decomposition. The experiment clearly demonstrates two major mechanisms involved in organic-matter protection: “chemical protection” and “physical protection.”^[48]

Chemical protection refers to the reduced availability to microorganisms (and therefore decomposition) of organic matter in soil due to chemical interactions with soil constituents, such as complexation or adsorption on reactive mineral surfaces. Many natural and contaminant organic compounds are not available to microorganisms when adsorbed.^[49–52] Models that best describe the decomposition of compounds in soil couple biodegradation with sorption and assume that adsorbed compounds are not degraded.^[53] While some organisms can access some adsorbed compounds, the rate of decomposition is largely controlled by the desorption of the compound.^[53,54] The effect of minerals is also indirect because extracellular enzymes adsorb to clay minerals and become inactivated.^[55]

The physical protection of organic matter is the reduction in organic-matter decomposition rates caused by the architecture of the organo-mineral soil matrix. Evidence of physical protection comes primarily from experiments or agronomic situations in which soil structure is disrupted, leading to a flush of mineralization.^[25,56–58] A large proportion of labile soil organic matter appears to be physically protected in microaggregates.^[56] Some degree of contact between a microorganism or extracellular enzyme and the organic substrate is needed to allow biodegradation. Soil microorganisms generally occupy less than 2% of soil surface area and less than 1% of soil porosity.^[14] Therefore, large distances can exist between organism and substrate. Soil structure controls the continuity of pores filled with water and their accessibility to microorganisms. Habitable pore space consists of 15–25% of the total porosity, while the remainder is inaccessible to microorganisms because pore necks are smaller than 0.2 μm or pores are air-filled

rather than water-filled.^[59] Furthermore, soil structure may create sites in which the local physico-chemical conditions are unfavorable to mineralization due to oxygen depletion in anoxic center of aggregates.^[60]

While the chemical protection provided by adsorption is often permanent, physical protection is highly dynamic. Soil structure is continuously changing due to the action of soil fauna, root growth, wet–dry cycles, and tillage (see Fig. 3). Therefore, physical protection depends on the life expectancy of the arrangement of the protection sites and is therefore subject to changes due to soil aggregate turnover.^[61] While the relative contribution of physical protection to the stabilization of organic matter may be low, it often affords the time for more permanent chemical-protection mechanisms to occur.

CONCLUSION

The existence of “primary particles” and “clean” mineral surfaces in natural soils occurs only rarely (except in the case of sands). Instead, soil is an intimate association of organic matter and mineral surfaces that interact to various degrees. While the binding of organic matter with mineral surfaces occurs at the nano- to micrometer scale, its impact is felt upward to the centimeter and meter scales. Organo-mineral relationships are dynamic processes that alter the properties of both the organic matter and mineral particles involved.

North Carolina, U.S.A.*

Abstract

Oxisols are physically deep but nutrient poor and sparsely inhabited soils in the world. Most Oxisols are located in warm tropical areas with ustic or udic soil moisture regimes that permit the growth of one or two grain crops each year, without irrigation. Without lime and fertilizer, even subsistence slash and burn agriculture is not possible on the poorest Oxisols. With stable economic infrastructure and markets, chemical fertilizer and lime needed to initially correct natural chemical infertility and replace nutrients harvested, intensive mechanized agriculture and grazing of improved pastures are realities.

INTRODUCTION

The name Oxisol was introduced in 1960 to avoid connotations associated with laterite and associated terms.^[1] Oxisols are sandy loam or finer textured soils. Their subsoils have an apparent cation exchange capacity at pH 7 of 16 cmol/kg clay or less, have an apparent effective cation exchange capacity of 12 cmol/kg clay or less, and contain less than 10% calcium (Ca), magnesium (Mg), or potassium (K) bearing weatherable minerals in the 50–200 μm sand fraction. If the surface 18 cm contains less than 40% clay, the amount of clay in the subsoil must be less than 20% greater than the clay content of the surface 18 cm. If the surface 18 cm contains 40% or more clay, increased clay content with depth (i.e., a kandic horizon) is permitted provided that it contains less than 10% weatherable minerals.^[2]

Reaction and base saturation are not criteria for defining Oxisols. Most Oxisols are acidic in reaction and have low base saturation percentages, but some have high base saturation and neutral pH values. Most Oxisols have low silt content; low available water-holding capacity; low bulk density; strong, fine, and very fine granular structures; and a more rapid hydraulic conductivity than would be predicted by particle size class.

Almost all Oxisols are located within tropical latitudes and have average annual soil temperatures of 15°C or more. The mean soil temperature of June, July, and August differs by less than 6°C from that of December, January, and February. Oxisols are divided into five suborders according to their soil moisture regime (SMR):

1. Aquox (3% of all Oxisols) is poorly drained with aquatic conditions and most often located in depressions and seepage areas in association with other Oxisols.

2. Torrox (0.3% of all Oxisols) has an aridic SMR with less than 90 consecutive days of plant-available moisture in normal years.
3. Ustox (53% of all Oxisols) has an ustic SMR with from 90 to 270 consecutive days of plant-available moisture in normal years. One or two crop-growing seasons are possible each year.
4. Udox (32% of all Oxisols) has less than 90 consecutive days that are too dry for reliable crop growth in normal years. Two and sometimes three consecutive crops can be grown each year.
5. Perox (12% of all Oxisols) has rainfall that exceeds potential evapotranspiration every month of normal years. With no dry season, it is difficult to harvest grain crops, and slash and burn management is difficult because of non-availability of reliable time to burn.

GEOLOGIC SETTINGS

The most extensive contiguous areas of Oxisols are related to mid- to late-tertiary geomorphic surfaces composed of material that has been weathered, eroded, transported, and redeposited many times.^[3,4] The materials within which Oxisols form on such surfaces are those that are an accumulation of resistant minerals that have the properties of Oxisol subsoil at the time of their deposition. Such deposits, known as oxic soil material sometimes have stone lines of quartz and/or oxide-cemented gravel. The inert nature of oxic soil material precludes many pedogenic processes, and Oxisols are present on alluvial deposits of such material.^[5]

Oxisols also form on stable surfaces where easily weatherable materials, such as basic and ultrabasic rocks and geologically old volcanic deposits, are exposed to warm humid conditions.^[6,7] These occurrences are generally of limited spatial extent.

PROCESSES OF FORMATION

Processes that concentrate aluminum (Al) and deplete silicon (Si) favor the formation of oxic soil material. Low Si/Al ratios may have their origin in the magma of the earth's crust and persist when exposed to the soil environment. Si loss is to be expected in the surface of almost all soils, as rainwater infiltrates and moves through the surface layer. The amount of Si removed depends on the type of silicate mineral and residence time of water around the silicate mineral. Net Si loss results in destruction of 2:1 lattice clays and favors kaolinite, halloysite, and gibbsite enrichment.

Iron released by the dissolution of iron bearing silicates is concentrated as iron oxides unless reducing conditions are present. Almost all of the iron in Oxisols are present as iron oxides. Iron oxides impart many red, red-yellow, and yellow hues to soil. Red hues are indicative of hematite, while the yellow colors indicate goethite. Mixtures of these minerals have intermediate colors.^[8] Hematite is more easily reduced, and thus more readily dissolved, than goethite.^[9,10] Even short periods of reduction in microsites around decaying roots will, over time, cause the removal of hematite leaving goethite as the dominate iron oxide in the more yellow-colored Oxisols. If soil material is subjected to reducing conditions, all iron oxides are chemically reduced to soluble ferrous ions and removed, thereby leaving only the gray color of the clays and sand.^[11]

Oxisols contain more organic carbon than most other mineral soils.^[12] The organic carbon in the subsoil is relatively unavailable for microbial oxidation and masked by red- and yellow-colored iron oxides.^[13]

LOCATIONS

It is estimated that about 981 million hectares of the earth's surface is dominated by Oxisols. Of this 76% is in South America, 22% in Africa, and 2% in Asia. In South America, the central plateau between the Amazon and Paraná rivers and lower Amazon basin is perhaps the most extensive area of Oxisols. Multiple erosion-deposition cycles have created deep sedimentary deposits of material rich in quartz sand, iron, and Al oxides and 1:1 layer clays. Quartzipsamments are present in deposits too sandy to classify as Oxisols. The eastern part of the Amazon basin is filled with oxic materials eroded from adjacent plateaus and Oxisols predominate. In the western part of the Amazon basin, materials eroded from the Andes enrich the parent materials with weatherable minerals, and almost no Oxisols are present.^[14] In Central Africa, most Oxisols are in the central Congo River basin but seldom present in areas where relatively volcanic materials contribute to the present soil.

The presence of Oxisols within all SMRs and on formed geomorphic surfaces argues against generalizations about climatic and time factors necessary for Oxisol formation. The close association of Oxisols with parent materials

almost devoid of weatherable silicate minerals and the near absence of Oxisols in adjacent geologic materials clearly identify parent material composition as the controlling factor in Oxisol formation.

HUMAN USE

Oxisols are chemically infertile when compared to most other soils. Except when formed in basic and ultrabasic material, Oxisols are extremely poor in basic cations, and exchangeable Al dominates the cation exchange sites. Size and density of trees in undisturbed "cerrado" vegetation growing on Oxisols in Central Brazil are closely related to chemical fertility.^[15,16] Even the more highly base saturated "Eutro" great groups of Oxisols contain small total quantities of exchangeable Ca, Mg, and K.^[11] Phosphorous contents are relatively low, and phosphorus reacts with Al and iron oxides to such a degree that it is very slowly available to plant growth. Fast-growing food-crop plants seldom sustain satisfactory growth on unfertilized Oxisols.

Many of the relatively base-rich Oxisols support natural forest growth. Forest stands slowly accumulate plant-essential nutrients in their biomass. When a sufficient quantity of forest vegetation is cut, allowed to dry, and then burned, enough nutrients are rapidly released from the ashes to allow subsistence farmers to harvest one or two food crops. The site is then abandoned and a natural succession of woody vegetation that is able to grow with a slower rate of nutrient uptake than crop plants reestablishes. After several years, the biomass of the natural vegetation again acquires enough essential nutrients that subsistence farmers can repeat the slash and burn process.

On the least fertile Oxisols, only poor quality grass and shrub-type trees grow. An extensive area of this condition is the "cerrado" savanna vegetation in Central Brazil. The "cerrado" vegetation is so nutrient poor that the bones of grazing cattle deteriorate from Ca and phosphorous deficiency, unless supplemental mineral concentrates are used. Farmers attempting slash and burn techniques are discouraged by negligible yields. Inability to sustain indigenous human populations is a characteristic of the least fertile Oxisols.

With the advent of a clear understanding of chemical limitations and in those locations where economic stability enabled infrastructure necessary for commercial agriculture, an entirely different relationship of human interaction with Oxisols is possible. In 1992, with only 10 million hectares of the estimated 204 million hectares of Oxisol dominate "cerrado" cultivated, 28% of the grain production in Brazil was from the "cerrado" area.^[17] Beef production has rapidly increased in fertilized pastures. With market access, it is economically feasible to make initial applications of lime and phosphate fertilizer to overcome the natural acidity and phosphate fixation capacity of the most infertile Oxisols. Small amounts of

zinc, boron, molybdenum, and copper are needed on some sites. The initial application of lime and phosphate is mixed as deeply as possible to maximize a favorable rooting depth. Facilitated by the low cation capacity of the Oxisol, subsoil Ca moves downward, replaces exchangeable Al, increases the exchangeable Ca/Al ratio, and facilitates deeper root growth.^[18] The deeper rooting zone enhances the available moisture supply during rainless periods in the growing season. Total amounts of exchangeable Al in the subsoil are low, and relatively small amounts of Ca are required. Gypsum is especially favorable for Ca movement and supplies sulfur that is often needed in Oxisols. The initial investment in lime and phosphate fertilizer is large but not prohibitive. In subsequent years, nitrogen, phosphorous, and K fertilizers and lime are needed to replace nutrients exported in harvested crops and maintain desirable pH values, but annual amounts are no greater than on other soils growing similar crops.

Many Oxisol-dominated landscapes are nearly level, and trafficability for large equipment and road construction is facilitated by physically stable low activity silicate clay and iron oxide. Low indigenous populations facilitate the acquisition of large management units for efficient mechanized agriculture. Oxisols with ustic and udic SMRs and isothermic and isohyperthermic soil temperature regimes have reliable rains during at least one growing season each year, followed by a period of dryness as grain crops mature. The reliable onset of a dry season decreases the risk of grain spoilage and the cost of drying harvested grain and permits maximum efficiency of harvest equipment and marketing infrastructure.

CONCLUSION

Oxisols are physically deep but nutrient poor and sparsely inhabited soils in the world. Most Oxisols are located in warm tropical areas with ustic or udic SMRs that permit the growth of one or two grain crops each year, without irrigation. Without lime and fertilizer, even subsistence slash and burn agriculture is not possible on the poorest Oxisols. With stable economic infrastructure and markets, chemical fertilizer and lime needed to initially correct natural chemical infertility and replace nutrients harvested, intensive mechanized agriculture and grazing of improved pastures are realities.

Buenos Aires, Argentina

Abstract

The soils of the Pampas are mostly Mollisols under udic and thermic moisture and temperature regimes (Chernozems, Kastanozems, and Phaeozems under the Food and Agriculture Organization soil classification system) used for agricultural practices for continuous annual crops, integrated crops, and livestock or extensive livestock production systems. Wind and water soil erosion and soil organic matter and nutrient depletion are the major constraints for crop production. For the management of these limitations, the use of no-till production systems, crop rotations, and fertilization and inoculation for legumes practices are recommended for the establishment of sustainable production systems. However, more research is required for the development of integrated nutrient and crop management practices for the different crop sequences within the subregions of the Pampas.

INTRODUCTION

The Pampas region is a vast plain of approximately 52 Mha located along the central part of Argentina. It is an extension of a bigger plain wedged between the Andes in the West and the Guyana–Brazilian shield in the east including the Venezuelan llanos, the Amazonian lowlands, and the Chaco–Pampas region. According to rainfall and soil quality patterns,^[1] the Pampas can be divided into five subregions: Rolling Pampas, Inland or Central Pampas, Southern Pampas, Flooded Pampas, and Mesopotamian Pampas (Fig. 1).

The climate is warm temperate with adequate to less than adequate rainfall for normal crop production. The mean temperature is 18°C and 14°C in the north and the south of the Pampas, respectively.^[2] In part of the region, the temperature and the frost-free period are adequate for growing double crops (i.e., soybean or maize planted after wheat). Rainfall amounts show high inter-annual variability. Most rainfall occurs between October and April (spring to fall seasons), and the long-term annual average is 500 and 1000 mm in the southwest and in the northeast of the region, respectively.^[2] Although there has been an increase in precipitation, at the rate of 100 mm per year,^[3] the water balance during the summer is negative with long periods of droughts of 2–6 weeks.

Most of the region was originally covered by grasslands, interrupted only by gallery forests along the margins of the Paraná, Uruguay, and La Plata rivers. Most of the region is under agricultural land use and, excluding the flooded Pampas, covers approximately 34 Mha. Almost

60% of the agricultural area is covered by perennial pastures comprising alfalfa (*Medicago sativa* L.), fescue (*Festuca arundinacea* L.), and other grasses under direct grazing livestock systems. The rest of the area is involved in the annual crop production, comprising 10 Mha of soybean [*Glycine max* (L.) Merrill], 2.4 Mha of maize (*Zea mays* L.), 6.3 Mha of wheat (*Triticum aestivum* L.), 1.8 Mha of sunflower (*Helianthus annuus* L.), and other crops.^[4] In the rolling Pampas and in the eastern parts of the inland Pampas, almost 100% of the area falls under the annual crop sequences while the proportion of area covered by pastures increases toward the boundaries of the Pampas. The flooded Pampas is mostly under native grasslands for cattle production systems.

MAIN SOILS OF THE PAMPAS

The parent materials are homogeneous comprising Pleistocene and Holocene Loessial sediments, with variation in texture according to the distance from the Andes, being sandier to the southwest of the Pampas. The mineralogy of the coarse fractions is dominated by the almost unweathered volcanic material (volcanic glasses) and plagioclases and lithic fragments and has a minor proportion of quartz and orthoclases. The clay fraction of the topsoil contains mostly illite along with kaolinite and illite–smectites intergrades (rarely well-crystallized montmorillonite).^[2]

The most frequent cropped soils of the Pampas are Mollisols, with prevailing udic and thermic moisture and

temperature regimes [mostly Chernozems, Kastanozems, and Phaeozems after the Food and Agriculture Organization (FAO) classification system]. A summary of prevailing soil associations within each subregion of the Pampas is presented in [Table 1](#). In general, surface soil is moderately acidic with a high base saturation dominated by Ca^{2+} and K^+ .^[2] Soil organic matter (SOM) is a relevant soil property related to crop productivity because of its contribution to the soil structure, water-holding capacity, and nutrient supply.^[5] The SOM of the top layer decreases from almost 40 g/kg to less than 15 g/kg from northeast to southwest. A change in texture of the soil, i.e., from a fine to coarse texture, is noticed along the northeast to southwest direction.^[6] Nitrogen (N) and to a lesser extent phosphorus (P) supply are low for normal crop production in most of the areas along the Pampas region. In localized areas, sulfur and several micronutrients (i.e., boron, chloride, and zinc) are deficient for high yielding crops. From the point of view of crop production, water storage capacity is an important differentiating factor among soil types in the Pampas. Potential available water in the top 100 cm is 83 and 172 mm on Entic Haplustolls and Vertic Argiudolls, respectively.^[2] Shallow soils have a serious limitation to crop production in the Southern Pampas, where the topsoil depth is less than 50 cm in approximately 50% of the areas because of the presence of a petrocalcic horizon ([Figs. 2–4](#)).

SOIL RELATED CONSTRAINTS TO CROP PRODUCTION

Soils of the Pampas are susceptible to erosion by water and wind. Erosion by water predominates in the Rolling and the Mesopotamian Pampas where intensive rainfalls, silty topsoil textures, and long slopes predominate.^[2] Wind erosion, caused by a combination of tillage operations and strong winds during the dry season (winter), is a severe hazard in the west part of the Inland and the Southern Pampas.^[7] In shallow depressions, in the Inland Pampas, temporary ponds of water and saline soils are frequently observed. In saline patches, salts are leached down the profile in years with normal rainfall. The area under severe saline conditions is reduced and located close to permanent water formations.

SOM declines are mostly associated with annual row crop production systems using tillage.^[7] The use of soil pastures in rotation with annual crops contributes to recover SOM levels, and it is a widely adopted production system toward the marginal areas of the Pampas.^[2,7] The use of no-tillage practices, mostly for annual crops, is increasing every year and it contributes, among other factors, to the conservation of SOM levels.^[8,9]

The risk of topsoil compaction by machinery traffic increases in areas having low SOM levels and high silt content. The risk of compaction is more toward the Rolling

and the Mesopotamian Pampas and when summer crops are harvested soon after the rains.^[12]

Grain yields of crops and livestock production per unit of area are increasing every year.^[4] However, replacement of nutrients harvested in the grains and other agricultural products is lower than the amount applied by fertilizers. On average, only an equivalent of 40% of the P in the grains harvested in major crops of the Pampas is applied annually with the fertilizers. Thus, the area with

Fig. 3 Typic Ustisamment.

Fig. 4 Typical Argiudoll.

extractable P deficiency has increased from less than 50% to almost 80% of the Pampas between the late 1970s and the end of the 1990s (Fig. 5).^[13,14]

MANAGEMENT OPTIONS FOR SUSTAINABLE LAND USE

No-till farming and crop sequences integrating cereals (i.e., maize and wheat) with oil crops (i.e., soybean and sunflower) are the recommended management practices for sustainable land use in most of the Pampas.

Fig. 5 Wind erosion in central Pampas.

But, toward the marginal boundaries of the region (i.e., west part of the Inland Pampas and the southwest of Southern Pampas), the rotation of annual crops and perennial pastures under livestock production is recommended. Numerous research and extension reports show that the adoption of continuous no-till cropping practices, also in rotation with pastures, reduces soil erosion, conserves SOM, consolidates soil structure, reduces the risk of soil compaction, and improves productivity.^[8] Soil tillage increases the disturbance of soil, promotes the loss of SOM, and reduces its productivity in most of the region. Use of crop residue mulch is also recommended for conserving soil water. In the Mesopotamic Pampas, terracing and no-till cropping systems are the recommended soil management practices for decreasing the risk of soil erosion by water.

The efficient management of SOM and related properties depend on the lack of soil disturbance and carbon (C) input to the soil based on above- and below-ground productivity of the crops. In most of the Pampas, the use of N and P fertilizers are recommended for agronomically optimum crop production. In the case of soybean and other legumes (i.e., peanuts and alfalfa), an efficient and yearly use of inoculants providing selected strains of rizobia is also recommended (Fig. 6).

RESEARCH AND DEVELOPMENT PRIORITIES

During the last years, the agricultural practices broadly expanded from the grain belt (mostly in the Rolling Pampas) through the rest of the region. Because of market and ecological conditions, soybean is the most common crop and, despite the recommendation of growing it in rotation with cereals, is mostly planted as monoculture. Thus, focused research is needed for developing sustainable production systems capable of sequestering C and related beneficial effects on soil properties, along with high profit for

Fig. 6 Central or inland Pampas maize crop.

the farmers, so as to meet the competition arising out of the production of monoculture soybean.

Developing no-till production systems involving integration of annual crops and livestock production on marginal areas is a high priority. These lands have been under cultivation since the beginning of the 21st century. There is also a need to conduct research for strengthening the nutrient-cycling mechanisms within different production systems for improving the development of integrated nutrient management practices for different crop sequences and subregions of the Pampas.

CONCLUSION

The soils of the Pampas are mostly Mollisols under udic and thermic moisture and temperature regimes (Chernozems, Kastanozems, and Phaeozems under the FAO soil classification system) used for agricultural practices for continuous annual crops, integrated crops and livestock or extensive livestock production systems. Wind and water soil erosion and SOM and nutrient depletion are the major constraints for crop production. For the management of these limitations, the use of no-till production systems, crop rotations, and fertilization and inoculation for legumes practices are recommended for the establishment of sustainable production systems. However, more research is required for the development of integrated nutrient and crop management practices for the different crop sequences within the subregions of the Pampas.

Abstract

In the Pantanal, four pedological zones can be distinguished: 1) a Vertisols–Planosols–Solonetz area of Miranda, Aquidauana, Abobral, Nabileque, and Porto Murtinho subregions; 2) a Hydromorphic Podzol and Arenosols area in the central part, encompassing the alluvial fan of Taquari River (Paiguás and Nhecolândia subregions); 3) Plinthosol–Planosol area to the north of São Lourenço River (Barão de Melgaço, Poconé, and Cáceres subregions); and finally 4) the Gleisols/Alluvials of the Paraguai floodplain, where Hydromorphic Planosols and associated Solonetz are dominant (Paraguai subregion).

INTRODUCTION

The Pantanal is an extensive wetland located in the center of South America (16–21°S; 55–58°W), possessing an extraordinary variety of ecosystems, which constrains a general characterization of the area. Basically, it is a vast floodplain that is seasonally inundated, with approximately 140,000 km² in the Brazilian territory (Fig. 1), extending over Bolivia and Paraguay, and with low-lying relief, ranging from 80 to 150 m.

GEOLOGICAL AND CLIMATIC ASPECTS

The main feature of the area is an intracratonic tectonic depression infilled by Quaternary sediments and surrounded by crystalline rock terrains, which are the main water and sediment source area. Its formation is linked with later events of Andean orogeny, in the late Tertiary/early Quaternary, with intense block faulting, from the Miocene onward.^[1] The active subsidence of tectonic blocks in Central South America was accompanied by an upward movement of the “Bodoquena Platô Horst,” creating a rock barrier, which dammed the outlet of Paraguai River, and damming “lag” sediments within the depression of the Pantanal.^[2] The most abundant Quaternary deposits are interpreted as products of intense erosion of the bordering marginal plateaux, infilling the low-lying

Paraguai depression. In the early Quaternary, this basin was virtually endorheic. Then, the Taquari River, coming from highland areas of the Paraná/Araguaia/Amazonas watershed, broke its outlet onto the friable, soft sediments, building a vast sandy, alluvial fan under semiarid conditions.

This semiaridity prevailed during the early mid-Quaternary deposition of the “Pantanal Formation,” with a trend of increasing aridity. Eventually, increasing rainfall of late Quaternary time broke the dammed Paraguai, creating its outlet into the Paraná basin, with increasing water volume.

The climate is tropical subhumid (Aw, Koeppen) with mean annual temperature of 26°C, and rainfall in the range of 800–1200 mm.^[3]

SUBDIVISION OF THE PANTANAL AND HYDROLOGICAL ASPECTS

The geographic position of the Pantanal represents a crossroad between Amazonia, Chaco, Cerrado, and Atlantic Forest biomes, favoring the exchange of species.^[4] The interplay between complex biotic and abiotic factors resulted in high heterogeneity of landscapes within the plains, characterizing distinct subregions. On hydrological and geomorphological basis, the Pantanal is formed by 10 subregions.^[5] Reviewing the cartographic database,

Fig. 1 Localization of the Pantanal in South America.

11 subregions were identified;^[6] these are called the Pantanaís of Cáceres, Poconé, Barão de Melgaço, Paiaguás, Nhecolândia, Aquidauana, Miranda, Abobral, Paraguai, Nabileque, and Porto Murtinho (Fig. 2).^[7]

Local and regional climatic forces influence the hydrological behavior of the Pantanal. Rains are concentrated between October and March and usually lead to widespread flooding because of insufficient drainage outlet. In the north sector of the Pantanal, the high water level occurs during January–March, whereas the southern part is affected from April until June. The timing of the highest level is reached in February in the north, and in June in the south Pantanal, as a result of slow movement of Paraguai River waters.^[5]

The widespread floodings are time/space-constrained ecological phenomena, being variable with respect to intensity, duration, and depth. Extensive flooding may be due to either pluvial water or runoff from adjacent high plateau,

being exacerbated by high water-table level and sluggish movement of rivers in the Pantanal. Between half and a third of the Pantanal area is subjected to fluvial inundations, whereas the majority is due to local rainfall.^[8]

In this periodic inundation regime, hydromorphism is a dominant process, which is due to ill-drainage, which affects all soils of the Pantanal, especially those developed from alluvial sediments. High-nutrient inputs are prevalent only in fluvial inundation, whereas rains can cause extensive waterlogging without enrichment.

SOILS OF THE PANTANAL

The main soils of the Pantanal are Planosols, Hydromorphic Podzol, Plinthosols, Gleisols, solodized Solonetz, Vertisols, and Arenosols (hydromorphic or well-drained).

Fig. 3 Soils of the Pantanal.

Planosols are typically found in flat, low-lying terraces across the whole Pantanal, associated with dry savanna woodland. These soils are closely associated with sedimentary deposits of the Pantanal Formation (Quaternary), possessing shallow profiles under hydromorphic regimes. They show an argillic horizon with an abrupt contact with an overlying E, which is normally fractured along the horizontal contact during the dry period. The B horizon (planic) is dense and impervious, showing features related to seasonal ill-drainage, such as mottling and gleying. These soils commonly have a plinthic or petroplinthic character and can be either eutric or dystric. Most are solodic, due to the high sodium (Na) percentage of the cation exchange capacity (CEC), particularly in the south and northwest Pantanal. The agronomic importance is limited due to chemical and physical constraints, and natural pastures are the common land use.^[9–11]

Solodized Solonetz are soils with great similarities with the Planosols, but their B horizons present an even higher

Na saturation, which makes them sodic (or natric), which is associated with poor drainage conditions. Vegetation is called “Bosque Chaquenho,” characterized by xerophytic vegetations rich in cactaceae and deciduous trees mixed with savanna species and Carandá (*Copernicia* sp.), sometimes forming dense palm forests called “Carandazal.” They are often found in the south Pantanal in the Nabileque/Apa interfluves.^[9–11]

Plinthosols can be either hydromorphic or not but are always related to hard, dense subsoils with limited internal drainage. They have a plinthic horizon within the first 40 cm, and abundant mottling with greater depths. They are usually associated with open savanna grassland, being either dystric or eutric, depending on the parent material, but the former is dominant. They occur north of the Piquiri River and in the Paraguai depression.^[9]

Gleisols (humic or nonhumic) are hydromorphic mineral soil with a glei horizon not accompanied by a plinthic or an argillic one. They cannot have vertic, natric, or salic properties and are less important in the Pantanal lowlands

compared with the former hydromorphic soil classes. Vegetations on Gleisols are typically hydrophilous fields, and nutrient status varies considerably, but eutric types are dominant.^[9–11]

In the top of the well-drained uplands of the Pantanal, Arenosols (quartzous sands) are distinguished by sandy texture, little evolution, and A and C horizon sequences. They are very frequent in large extension of the Taquari alluvial fan, associated with ill-drained Hydromorphic Podzols in the lower landscape positions. The vegetation is closed savanna woodland, which progressively becomes grassy with high water-table level. The transition zone between the quartzous sands and Podzols is hydromorphic quartzous sands, always dystic and with very low CEC.^[9–11]

Vertisols are hydromorphic clayey soil, which occurs in the Pantanal wherever high activity clays formed from alluvium or wherever calcareous rocks are dominant, showing little horizonation (A–C). Their shrinking–swelling character gives them the typical vertic morphology, with slickensides and columnar structure, with or without calcium carbonate (CaCO₃). They are mostly associated with CaCO₃-rich sediments of the Xaraés Formation, being common between the Aquidauana and Paraguai Rivers, in the south Pantanal, and in the Cuiabá River, in the north Pantanal. The vegetation is dry forest with palms and cacti, and pastures are the dominant land use.^[9,10]

CONCLUSION

In the Pantanal, four pedological zones can be distinguished: 1) a Vertisols–Planosols–Solonetz area of Miranda, Aquidauana, Abobral, Nabileque, and Porto Murtinho subregions; 2) a Hydromorphic Podzol and Arenosols area in the central part, encompassing the alluvial fan of Taquari River (Paiaguás and Nhecolândia subregions); 3) Plinthosol–Planosol area to the north of São Lourenço River (Barão de Melgaço, Poconé, and Cáceres subregions); and finally 4) the Gleisols/Alluvials of the Paraguai floodplain, where Hydromorphic Planosols and associated Solonetz are dominant (Paraguai subregion).

University of Savoie, Savoy, France

Abstract

The Spanish word *páramo* refers to the deserted, windy, humid, and cold North Andean areas. This high-altitude grassland ecosystem, which has large plant diversity, covers 35,000 km² and is distributed as discontinuous islands between the high altitudinal forest and the permanent snow line. In the *Páramos*, soils evolve in relation with low temperature, high soil moisture, and aluminum availability of the parent rock. Carbon content and water retention are very high. *Páramos* soils are considered as a “sponge” which enhance water retention and buffer the water flow downstream. However, new agricultural practices modify soil properties, altering infiltration and runoff regime and disturbing the primary hydrological function of the *Páramos*.

PÁRAMOS ENVIRONMENT

Páramo Location

The Páramo is located in intertropical Central and South America, between 11° latitude north and 8° latitude south (Fig. 1), mainly situated in Colombia (14,500 km²), in Ecuador (12,600 km²) but also in Venezuela with small extensions in Costa Rica, Panama, and Northern Peru (Table 1).^[1–3] It occurs at an altitude generally ranging between 3200 and 4800 m.

Páramos Climate

With an average decrease of 0.6°C for 100 m change in elevation, temperatures are cold with an annual average of 9°C at 3500 m. Day–night amplitude is over 15°C with temperatures dropping randomly below 0°C over 4200 m. Annual variation is very low.

The windward external sides of the cordilleras receive more rainfall than the leeward internal sides (interandean valleys side), where rainfall increases with altitude. Annual Precipitation ranges between 1000 and 1500 mm with extremes between 500 and 3000 mm. In the northern tropical areas, the rainfall has a unimodal distribution with one dry season, in the southern area closer to the equator, rainfall occurs all year long with a bimodal distribution of two drier seasons. Intensities are very low, rarely exceeding 40 mm/day. Frequent fogs, drizzles, and hailstorms contribute to maintain a humid climate, and air moisture ranges between 70% and saturation.^[4]

Páramos Vegetation

The Páramo is a grassland biotic formation of the high Andes and contains between 3000 and 4000 species of vascular plants with 60% estimated endemism.^[5]

The vegetation of the Páramos can be divided into three belts:^[3]

1. The *super-Páramo*, at high altitudes ranging between 4200 and 4800 m, represents a periglacial environment with sparse vegetation cover and species adapted to nocturnal freezing and high solar radiation by leaf xeromorphic adaptation (reduced surfaces, folded, densely woolly, whitish leaves).
2. The *proper-Páramo* (3500–4200 m) has an open-type vegetation dominated by bunchgrasses (tussocks). Poaceae (*Calamagrostis* sp. and *Festuca* sp.) and dwarfed bamboos form the *pajonal* and cover 70% of the soil surface. The giant rosettes are the most remarkable plants [*Espeletia* sp. (Fig. 2) and *Puya* sp.]. Acaulescent rosettes, cushion-like vegetation (especially in swampy areas), and some shrubs complete vegetation. Patches of forest (*Polylepis* sp.) grow up to an altitude of 4200 m.
3. The *sub-Páramo* (3200–3500 m) is a transitional zone between the Páramo and the Andean forest; the coverage of small trees and scrubs is greater than in the proper-Páramo. The sub-Paramo surface extends toward lower altitude with human land clearing to provide pasture and farmland.

Geology–Geomorphology

The Páramos follow the summital portion of the main northern Andes Mountain chain. The most important part of this belt from the center of Colombia to the center of Ecuador has a strong volcanic activity. Ash falls are mainly rhyodacitic to andesitic in composition and cover the basement of the Andean belt made of sedimentary or metamorphic rocks.

The geomorphology of the Páramo was modeled by glacier extension during the major glacier phases at altitudes of over 4000 m, with large U-formed valleys, many lakes and smoothened relieves.^[4] Two main forms can be distinguished: 1) highly erodible forms affected by volcanic ash deposits, with uniformed small hills of convex

Fig. 2 Profile of a Melanudand in the *Páramo* of the ecological reserve of El Angel, Carchi province, north of Ecuador.

concave forms, gentle slopes, and isolated volcanic cones (>5000 m in altitude) emerging from these chains and 2) non-volcanic rocks or hard lava flows with notched summits and steep slopes.^[4]

SOILS

Páramos soils have been described by Jenny since 1948.^[6] Soils evolve in function of the convergent effects of low temperature, high soil moisture, and aluminum (Al) availability.^[7]

In the supra-*Páramo*, organic matter production decreases with altitude, and soils are very shallow, with umbric epipedon^[8] and periglacial features. In non-volcanic Venezuelan areas, Cryepts are dominant. The presence of giant rosette plants gives the soil pattern discontinuous properties with higher carbon (C) content only at soil surface and around the rosette.^[9] In volcanic areas, during glacier periods, ice caps protected soils from ash deposits. The deposits are weakly weathered and form Vitrandic Cryents.

At lower altitudes, in humid conditions, the availability of Al is the second important factor in soil formation. When Al availability is very low, Humods and Fragiaquods are observed on gneiss and micaschists rich in quartz (Podocarpus *Paramo* in the south of Ecuador). With higher Al availability, Inceptisols (Dystrudept) form with an

umbric epipedon. With high Al availability, Al forms very stable complexes with organic matter.^[10] The main pedological process is an acidic complexolitic andosolization with Al + 1/2 Fe oxalate extract >2% and Al% pyrophosphate/Al% oxalate >0.5 characteristic of non-allophanic Andisols,^[11] which are the more extended soil types in the *Páramos*. On volcanic ashes, important Al availability leads to a very fast soil formation, with Vitrands forming in less than 1000 years. The farther the deposits are from their emission source, the finer are the ashes, and the faster is the rate of weathering. The older, most evolved soil profiles (± 3000 years) have the lowest base reserve and can be classified as Udands. The non-allophanic andosolization process could also be active on nonvolcanic Al-rich substrates (paleo-Oxisols or metamorphic rocks). All of these soils are acidic and have anionic retention capacities (especially for phosphorous and sulfur).

***Páramo* Soils and C Content**

All *Páramo* soils are very rich in organic C. In the *Paramo* of Northern Peru, soils contain over 10 kg m⁻² C, whatever the nature of the parent rock (limestones, volcanic rocks, or sandstones).^[12] Low temperatures and stable organo-metallic complexes^[7] reduce the biological activity and therefore decrease the rate of organic matter mineralization. High C accumulation results from different pedologic processes on successive ash layers but also on colluvial buried soils on steep slopes. C sequestration can exceed 85 kg m⁻² in the polygenic non-allophanic matured Andisols of Northern Ecuador (Table 2, Fig. 2).^[13] Altitude increases the soil organic C content with a maximum density (reaching 10 g cm⁻³) at around 3900 m. These Andisols have black thick melanic epipedon attributed to the presence of humic acids produced by the degradation of Poaceae family plants^[11] and can be classified as Melanudands (Fig. 2).^[8]

***Páramos* and Water Cycle Regulation**

The water content in non-allophanic Andisols at 1500 kPa is over 1000 g kg⁻¹ (hydic properties)^[8] and can be 2000 g kg⁻¹ at field capacity. The formation of an organo-metallic complex network leads to important microporosity. The more mature the soils, the richer they are in humic substances, and the higher is their microporosity. For matured Andisols, micropores with a radius <0.1 μ m can form over 50% of the soil volume.^[14] Water content is

Table 2 C Pool (kg m⁻²) of some *Páramos* soils

stable all year long. The measured hydraulic conductivity of this mature Andisol reaches 60 mm hr^{-1} and runoff is unlikely.

After drying, a new and extremely rigid structure appears: drying is therefore partially irreversible. As porosity increases, so does sensitivity to modification of the pores architecture and the loss of water-storage properties after drying.^[14] Water-repellent surfaces develop during drying.

Degradation of the Páramo Soils

More than half of the *Páramos* surface was used as extended land with an increasing rural population for grazing and cultivation. First, burning formed temporary bare surfaces,^[2,15] which are receptive to structural decay by the kinetic energy of raindrops or hailstorms. Second, black C-rich bare surfaces absorb solar radiation, which favors irreversible drying and water repellency at soil surface. The upper 20 cm of Andisols are deeply affected with a convergent decrease of more than a third of their original value in C, water, and Al contents. A highly water-repellent soil microstructure replaces the stable macrostructure.^[16]

After tillage, juvenile vitric Andisols crust and runoff coefficient increases by a factor of 3. On mature Andisols, soil packing and the development of water repellence lead to severe decrease in hydraulic conductivity. At the same time, soil loss is very high (over 1500 g m^{-2}) and occurs via the entrainment of hydrophobic aggregates in the surface runoff.

CONCLUSION

Though covering relatively small surfaces, paramos soils present specific properties in water retention and C sequestration. Any degradation or inappropriate land use alters these soils durably with a negative effect on the water availability for a large population living downstream.

Particle Density

Keith R.J. Smettem

Soil Science and Plant Nutrition, University of Western Australia, Nedlands,
Western Australia, Australia

Abstract

This entry gives an overview of particle density and standard methods for measurement.

INTRODUCTION

Density is a standard physical term defined as weight (mass) per unit volume. In soils, the density of the solid particles in a particular sample is referred to as the particle density. SI units are kilograms per cubic meter, but the fractional units of grams per cubic meter are also used ($1 \text{ g cm}^{-3} = 1 \text{ Mg m}^{-3}$). In most soils, the average density of particles, ρ_s , is in the range $2.6\text{--}2.7 \text{ Mg m}^{-3}$. This narrow range reflects the predominance of quartz and clay minerals in the soil matrix. An average particle density of 2.65 Mg m^{-3} (the density of quartz) is often applied to soils comprising principally silicate materials. Exceptions can occur if the soil is high in organic matter, which reduces the soil particle density. Humus, e.g., has a density that is usually less than 1.5 Mg m^{-3} . Conversely, soils that are rich in iron can have high particle densities. Ferromagnesian minerals, e.g., have densities ranging from 2.9 to 3.5 Mg m^{-3} . Density of iron oxides and other so-called heavy minerals can exceed 4 Mg m^{-3} .

Ovendry soil is essentially a two-phase porous medium comprising air and solids. The porosity can be determined if the bulk density (ρ_b ; the ratio of the mass of dry solids to the bulk volume of the soil) and the particle density are known. The porosity, ϵ , is then given by the following equation:

$$\epsilon = 1 - \rho_b / \rho_s \quad (1)$$

The particle density is also necessary for the calculation of sedimentation parameter required for the estimation of particle size by sedimentation methods.^[1,2] It is also used to determine the particle settling velocity in studies of sediment deposition from flowing water.^[3]

MEASUREMENT OF PARTICLE DENSITY

Widely accepted standard methods are available for measuring the weighted mean particle density of a sample^[4] and are based on measuring the mass and volume. The

mass is determined by weighing, and the volume is then calculated from the mass and density of a fluid displaced by the sample. The two most common methods of measuring particle density are the pycnometer method^[5] and the submersion method.^[6]

A pycnometer is a specific gravity flask that is sometimes fitted with a thermometer. For large samples, a volumetric flask may also be used with sufficient measurement accuracy for most applications. In brief, the method involves careful weighing to obtain the particle density from the following equation:

$$\rho_s = \rho_w (W_s - W_a) / [W_{sw} - (W_s - W_a)] \quad (2)$$

where ρ_w is the density of water at the observed temperature, W_s is the pycnometer weight containing a soil sample at oven-dry water content, W_a is the empty (air-filled) pycnometer weight, W_{sw} is the pycnometer weight when filled with soil and water, and W_w is the pycnometer weight when filled with water at the observed temperature. Note that the denominator represents the volume of water displaced by the soil particles.

The soil in the pycnometer is covered with a layer of water and evacuated to ensure complete saturation of the soil before topping up the pycnometer. Note that de-aired distilled water is used throughout the procedure, and organic matter is generally removed prior to use.

An air pycnometer can be used as an alternative method, particularly if it is important to retain organic matter in the sample. The method uses gas rather than water as the displacing fluid and the ideal gas law to calculate the volume of solids. Care must be taken to ensure that the procedure is performed at a constant temperature.

The submersion method involves measuring the volumetric displacement of water or a non-polar liquid by a soil sample of known air-dry weight. The samples of air-dried soil, usually about 25 g in weight, are formed into spaghetti-like threads by moistening to a plastic consistency and forcing through a 2-mm sieve. After oven-drying at 105°C and cooling in a desiccator, the prepared sample is placed in a weighing dish attached to a weighing beam by a thin

wire, and both the dish and the sample are immersed in a container of liquid. The particle density then follows from the equation:

$$\rho_s = \rho_l(W_{sd} - W_d) / [(W_{sd} - W_d) - (W_{sdl} - W_{dl})] \quad (3)$$

where ρ_l is the density of water or organic liquid used, W_{sd} is the oven-dried weight of both the soil and the weighing dish, W_d is the weight of the weighing dish, W_{sdl} is the weight of sample and weighing dish submerged in liquid, and W_{dl} is the weight of the submerged dish without the soil sample.

The submersion method sacrifices some precision compared to the pycnometer method but is easy to perform and has the advantage of being less laborious. The method cannot, however, be used with sandy soils because coherence is usually too low to allow the spaghetti-like sample threads to be prepared.

The particle density of finely divided active soil measured in water is usually greater than that measured in a non-polar liquid.^[4] As the proportion of minerals with expanding lattices increases in a given sample, so too does the specific gravity.^[4] Water density is also known to be affected by the surfaces of finely divided particles, so a more accurate measure of particle density would be obtained using a non-polar inorganic liquid in a pycnometer.^[4] However, if the particle density information is required in order to determine the volume of solids in a soil in contact with water, then it is logical to use water as the measurement liquid.

If the soil is high in organic matter, then it is easier to achieve wetting using a non-polar organic liquid. Organic particles also have a tendency to be buoyant in water, whereas they sediment more readily in non-polar liquids. This is obviously an advantage when attempting to measure the weight of a submerged sample.

The density of a suspension can also be measured very precisely using a vibrating tube,^[7] which is filled with a

solution or suspension. The resonant frequency of the vibrating tube is directly related to the density of the suspension.

Abstract

Particle packing refers to arrangement of solids in a given volume. This is important in many fields. This entry discusses the packing characteristics of various mono- and multiple-size particles in a mixture. It also outlines the corrections for particle sphericity, roundness, and roughness.

INTRODUCTION

Packing refers to the arrangement of solids in a given volume. Packing is important in many different fields, including aeronautics, agriculture, ceramics, chemical engineering, chemistry, foundation engineering, electrical engineering, foods, geology, mechanical engineering, medicine, pharmaceuticals, and polymer science.^[1] A few specific applications include packing of solid fuel for rockets and missiles, packing and storage of seeds, strength of powder compacts, packing of fluidized beds, packing of soil and roadway foundations, packing of pharmaceutical pills, and strengths of polymer structure. The underlying premise of packing is to identify the most efficient way of packing solids (whether it be particles, aggregates, powder, solid fuel, fruits, etc.) such that it provides maximum strength, uses minimum space, maximizes the efficiency of chemical reaction, and/or minimizes the shipping costs. In soils, geology, and hydrology, packing is important in understanding and quantifying the pathways of water and chemical transport and the sites of their retention.

INDICES OF PACKING

There are several indices that can be used to characterize particle packing. These include bulk density (ρ_b), void ratio (e), and porosity (f) as follows:

$$\rho_b = \frac{\text{mass of particles}}{\text{bulk volume}} \quad (1)$$

$$e = \frac{\text{volume of voids}}{\text{volume of particles}} \quad (2)$$

$$f = \frac{\text{volume of voids}}{\text{bulk volume}} \quad (3)$$

The above three indices are related to one another through their relationship with particle density (ρ_p).

$$f = \left(1 - \frac{\rho_b}{\rho_p}\right) = \frac{e}{1 + e} \quad (4)$$

$$\rho_p = \frac{\text{mass of particles}}{\text{volume of particles}} \quad (5)$$

In some fields, packing density has also been expressed as fractional density—defined as a fraction of the theoretical density of the material. Another index that characterizes a packing arrangement is the coordination number, the number of neighboring particles touching a given particle.

TYPES OF PACKING

Particle packing can be geometrically systematic (regular) or random (disordered). There are five different ways of systematically packing spherical particles of one size. These are cubic, cubical-tetrahedral, tetragonal-sphenoidal, pyramidal, and tetrahedral.^[2] Over the years, different terminology has been used to describe these packing arrangements. Graton and Fraser^[3] defined these packing arrangements as cubical, orthorhombic, rhombohedral, tetragonal-sphenoidal, and rhombohedral, respectively. White and Walton^[4] defined them as cubical, single stagger, double stagger, pyramidal, and tetrahedral, respectively (Fig. 1).

In cubical packing, spheres are arranged at 90° angles (Fig. 2). Each sphere touches four spheres in the same layer and one sphere in the layer above and one sphere in the layer below. Therefore, the coordination number for the cubical packing is 6 (Table 1). For other packing

Fig. 1 The full circles represent spheres in one plane while the dotted circles represent the spheres in the layer above.

arrangements, the coordination number varies from 8 to 12 (Table 1).

PACKING DENSITY

The packing density or porosity of a given packing arrangement can be calculated by knowing the geometry of packing. For example, in cubic packing, each sphere (with diameter of $2r$) is surrounded by an imaginary cube (unit prism) with a unit volume equal to $8r^3$. As the volume of the sphere is $(4/3)\pi r^3$, the porosity and void ratio of the cubical packing are as follows:

$$f = \frac{8r^3 - (4/3)\pi r^3}{8r^3} = \left(1 - \frac{\pi}{6}\right) = 0.4764 \quad (6)$$

$$e = \frac{8r^3 - (4/3)\pi r^3}{4/3(\pi)r^3} = \left(\frac{\pi}{7} - 1\right) = 0.9099 \quad (7)$$

Similar calculations of porosity for other types of packing arrangements have been made by White and Walton^[4] and are listed in Table 1.

Porosities listed in Table 1 are independent of sphere radius. Cubical is the loosest and pyramidal and tetrahedral and the densest packing of any spherical particles of a given size. Additional reduction in the earlier

Fig. 2 Angle at which particles are aligned in cubical and cubical-tetrahedral packing.

discussed porosities can occur by filling the irregular void spaces between the primary particles with smaller secondary, tertiary, quaternary, and quinary spheres. White and Walton^[4] showed that the porosity of tetrahedral packing can be reduced to as low as 3.9% (Table 2) through the introduction of smaller particles. Similar reductions in porosity are also possible for other packing arrangements.

MODELS OF PARTICLE PACKING

Over the years, attempts have been made to predict the packing density of a mixture of particles varying in diameter. Westman and Hugill^[5] and later Bodman and Constantin^[6] and Staples^[7] showed that one could approximate the packing density of a mixture of two or more particle fractions using an analytical expression based on the packing density of individual fractions. The assumption underlying this method is that if larger particles are dominant, then the contribution of the finer particles to bulk volume is minimal. However, if the finer particles are dominant, then the bulk volume of the mixture is equal to the bulk volume of finer particles plus the particle volume of larger particles. Extrapolating these two assumptions to various proportions of coarse and finer particles then leads to the identification of an optimum mixture of coarse and fine particles that can result in maximum density.

The analytical model has been described in Fig. 3.^[5] The abscissa refers to the volume fraction of coarse (X_1) and fine (X_2) particles, whereas the ordinate refers to particle volume, void volume, and bulk volume of coarse and fine fractions. Points C and F refer to the bulk volume of coarse and fine fractions when packed individually. If these fractions are stacked one above the other without mixing, then the bulk volume of the mixture is given by the line CF. Lines CE and HE refer to the particle and bulk volumes of the coarse fraction, respectively. Lines FD and GD refer to particle and bulk volumes of the fine fraction, respectively. If the coarse fraction dominates the mixture then the fine particles will be enclosed in the voids of the coarse fraction. The bulk volume describing this relationship is line CE. If on the other hand, the fine fraction is dominant, then the addition of any coarse particles adds to the bulk volume the equivalent of the particle volume of the coarse fraction. The line FH then describes the bulk volume of the mixture. The intersection of lines CE and FH defines the volume fraction of coarse and fine particles with the minimum bulk volume or the maximum packing density.

In Fig. 3, we assumed that the particle density of both fractions was the same. If there is a difference in particle density of various fractions then the ordinate can be expressed in normalized volume by dividing the bulk volume by the particle volume. Equations of the two

Table 1 Various types of systematic packing and the corresponding coordination number, radius of the largest cavity, volume of unit prism, porosity, and void ratio.

Type of packing	Coordination number	Radius of largest cavity	Volume of unit prism	Porosity	Void ratio
Cubical	6	$0.732r^a$	$8r^3$	0.4764	0.9099
Cubical–tetrahedral	8	$0.528r$	$4r^3 \times 3$	0.3955	0.6540
Tetragonal–sphenoidal	10	$0.285r$	$6r^3$	0.3020	0.4324
Pyramidal	12	$0.414r$	$4r^3 \times 2$	0.2595	0.3504
Tetrahedral	12	$0.414r$	$4r^3 \times 2$	0.2595	0.3504

^a r is the radius of the packing particles.

lines (CE and FH), along with the assumption that the sum of the volume fraction of the two components is 1.0, help define the minimum volume or the maximum density.^[5]

Gupta and Larson^[8] presented a computer model that simulated maximum, random, and minimum bulk densities of a soil based on the particle size distribution and the packing density of individual fractions. The packing model is based on the concept that certain particles (donor) will be enclosed in the voids of the packing assemblages of other particles (acceptor) of larger radii. The decision to designate which particle fraction acts as the acceptor and which acts as the donor depends upon whether the maximum density or random density is to be predicted. The model uses the cavity radius of stable packing arrangements (tetragonal or pyramidal–tetrahedral) as a guide in deciding when donor fractions can be fitted into the voids of the acceptor fractions.

Maximum density refers to the conditions when all the voids of the coarse fractions are systematically filled with finer fractions. Random density refers to conditions when particle fractions are randomly selected as acceptor or donor particles. Minimum density refers to conditions when all the fractions are acceptor particles and there is no mixing between the fractions.

Gupta and Larson^[8] tested the predictions of random packing from the packing model against the measured values for 22 mixtures of various size glass beads^[7] and 43 soils and dredged sediment mixtures. In many cases, the predicted bulk densities were close to the

measured values. Spivey et al.^[9] showed that artificially compacted (at 2 MPa) bulk densities of coastal plain soils in the southeastern United States compared well with random bulk densities predicted from the packing model. Reinsh and Grossman^[10] showed that mean bulk densities estimated from the packing model were an acceptable approximation of oven-dry bulk densities after inundation.

Gupta and Larson^[11] also extended the packing model to predict the bulk density of artificially prepared aggregated soils consisting of aggregates that varied in diameter from 0.053 to 50.8 mm. For aggregate size distributions varying in geometric mean diameter from 0.52 to 9.06 mm, the random packing density of aggregated soils was within 0.17 Mg/m^3 of the measured values.

With the availability of high-speed computing, there have been several advances in modeling particle packing. These advances have been summarized in a review article by Davis.^[12]

PARTICLE SHAPE EFFECTS

Concepts of particle packing have generally been developed assuming the particles to be spherical. Next to the particle size distribution, the shape of the particles has a major influence on the packing density of granular materials. Particle shape can be described by parameters such as sphericity and roundness.^[13,14] Sphericity refers to the degree to which particles approach spherical shape,

Table 2 Radius of secondary (B), tertiary (C), quaternary (D), and quinary (E) particles that can fit in the irregular spaces between the primary (A) particles in tetrahedral packing and the corresponding porosities.

	A	B	C	D	E	Filler
Radius of sphere	r	$0.414r$	$0.225r$	$0.177r$	$0.116r$	Very small

whereas roundness describes the angularity of particle corners. Wadell^[15] defined the sphericity index as the ratio of the surface area of a sphere (with the same volume as the test particle) to the surface area of the test particle. Riley^[16] defined the sphericity as the ratio of the diameter of the smallest circumscribing circle to the largest inscribed circle. The closer the particles are to a perfect sphere, the larger the sphericity index. German^[1] calculated the sphericity index of various shapes using Wadell's procedure.^[15,17] The sphericity index

Fig. 4 Effect of particle shape and smoothness on random fractional packing density. A common method of assessing particle roundness is to compare images of individual particles to standard charts showing particles with varying roundness. German showed that packing density increases with an increase in roundness of randomly packed monosized particles (Fig. 5). **Source:** From German,^[1] Krumbein,^[13] and Griffiths.^[14]

Fig. 5 Variation in fractional density vs. roundness of randomly packed monosized particles.

Source: Adapted from German.^[1]

varied from 0.87 for a cylinder of 1:1 diameter to length, 0.83 for a cylinder of 1:2 diameter to length, 0.47 for a disk of 5:1 diameter to thickness, 0.81 for a cube, and 0.76 for a rectangle of 2:2:1 length, width, and height ratio. German^[1] showed that for monosized particles, the particle packing increases with an increase in the sphericity of the particles (Fig. 4).

Another particle shape parameter affecting packing density is the surface roughness. This parameter refers to inter-particle friction owing to irregularities on the particle surface.^[1] German^[1] showed that the greater the surface roughness, the lower the particle density of monosized particles (Fig. 4).

CONCLUSION

Particle packing refers to arrangement of solids in a given volume. This is important in many fields. This entry discusses the packing characteristics of various mono- and multiple-size particles in a mixture. It also outlines the corrections for particle sphericity, roundness, and roughness.

Particle Shape

Brian M. Schafer

Agriculture and Horticulture, University of Queensland, Blue Mountain Heights, Queensland, Australia

Abstract

Particle shape classes and secondary clay mineral content have been used in combination to determine soil texture grades. Texture grades and their arrangement in soil structure largely determine pore volume in soils, which can be related to water and air-filled porosity as well as soil strength which has implications for soil–plant root relationships. Most of the use of particle shape analysis has been confined to soil genesis studies. These studies together with secondary clay mineral formation include the interpretations of initial parent materials, inferred factors, and processes used to describe the nature and genesis of soil particulate mineralogical properties and hence the distribution of contiguous soils in a landscape.

INTRODUCTION

Soil particle shape refers to the morphology of grains of essentially individual or composite mineral grains comprising the fine earth fraction of soil. The term “grain” has been used in geological literature to describe minerals ranging in size from 2 mm to submicroscopic dimensions, while mineral grains larger than 2 mm are classed as phenocrysts.^[1] In soils, particulate material is generally described as particles smaller than 2 mm average diameter being measured as the various ratios of a particle’s long, intermediate, and short axes.^[2] They are categorized into size classes that in turn are used to determine texture grades in soils. Generally, the particles are in tangential contact with each other rather than in continuous contact with their neighbors as found in igneous rocks and collectively determine soil fabric classes by virtue of their packing arrangement.

The use of size and shape analysis in soil science has been extended from sedimentary petrology origins to express the frequency distribution of size and shape ranges of particulate matter.^[3] They form an integral part of both structure and mineral analysis used to describe quantitatively and to interpret the origin and processes of the formation of soil material. Cementing materials such as carbonates and iron oxides are excluded except where they are formed separately from the soil matrix as secondary formations. Thus, most work in soil particle shape has been confined to primary minerals that are residual or transported from other sources. Secondary clay minerals also play a significant role in structure and mineral analysis. However, clay particle shape has not been subjected to the same analytical treatment as the coarser fractions.

Particle shape is related to size in that the size is reflected as volume expressed as true nominal diameter whereby the particles form an open 3-D network. This implies that the

particle volume has a porosity component determined by a packing arrangement of different diameter particles, but invariably leaving a residual pore space which can be filled with cementing agents, fluids, or air.

METHODS OF MEASUREMENT

Shape is based on the concept of sphericity and roundness.^[4–6] Sphericity is a description of the overall form of the particle irrespective of angularity of edges and corners, whereas roundness refers only to sharpness.^[3] Both of these properties have been defined mathematically.^[7,8]

Sphericity and roundness assessments are commonly made visually on individual grains and are tedious and imprecise because of the partly altered nature of minerals that makes it difficult to positively identify their origin in source material. They require the skills of optical mineralogy techniques and an appreciation of sedimentary petrology.

Particle shape analysis is usually performed on samples obtained from particle size analysis. This method results in separation of particles into grade scale classes based on a geometric scale. The broadness of the individual classes in the international grade scale tends to hide the continuum of sizes meaning that the nature of the size distribution cannot be determined from the grade scale classes. Consequently,

Table 1 Shape classes.

Class I	Disc	$b/a > 2/3$	$c/b < 2/3$
Class II	Spheroid	$b/a > 2/3$	$c/b > 2/3$
Class III	Blade	$b/a < 2/3$	$c/b < 2/3$
Class IV	Rod	$b/a < 2/3$	$c/b > 2/3$

^aBased on the class limits from the study by Powers.^[10]

Source: Adapted from Brewer.^[3]

shape analysis conducted on each size grade scale class also cannot be expressed as a function of the whole, and therefore, measurement is semiquantitative.

A number of grade scales have been proposed for shape analysis. Krumbein^[8] used a sphericity classification proposed by Zingg^[7] (Table 1), and Brewer^[3] suggested the addition of planar, acicular, and acicular-planar shape classes to this classification. Roundness grade scales have been proposed^[9–11] and are listed in Table 2. The scales are arbitrary divisions of a geometric scale of sizes or shapes (sphericity), so that each unit or grade serves as a class interval for analytical purposes. The units are mathematical derivations of particle diameter (millimeters) and phi scale^[3] and alternatively a rho scale.^[11] Combining sphericity and roundness scales has not been attempted, but the estimation of two parameters is used in defining particle shape.

PEDOGENESIS

Sphericity and roundness are the properties of particulate matter that have been used to interpret the abrasion effect of transport processes on specific detritus resulting from predominant physical comminution of source rocks and sedimentary bodies. The more spherical or rounder the particles, the greater the effect of abrasion and hence weathering and transport.

These processes are common in diagenesis and weathering processes associated with sedimentary rocks and sedimentary bodies (alluvium and colluvium) and are integral in the rock cycle of igneous, sedimentary, and metamorphic rocks.

In soils, shape analysis is used to determine uniformity of parent material and origin and mode of soil formation and used in mineral and structure analysis.

Soil-forming processes at or near the earth’s surface can then be inferred to link parent material origin and genesis of soil materials and soil profiles.

CONCLUSION

Particle shape classes and secondary clay mineral content have been used in combination to determine soil texture grades. Texture grades and their arrangement in soil structure largely determine pore volume in soils, which can be related to water and air-filled porosity as well as soil strength which has implications for soil–plant root relationships.

Most of the use of particle shape analysis has been confined to soil genesis studies. These studies together with secondary clay mineral formation include the interpretations of initial parent materials, inferred factors, and processes used to describe the nature and genesis of soil particulate mineralogical properties and hence the distribution of contiguous soils in a landscape.

Particle Size

Hwat Bing So

School of Agriculture and Food Sciences, University of Queensland, St. Lucia, Queensland, Australia

Harold R. Geering

Department of Agricultural Chemistry, University of Sydney, Sydney, New South Wales, Australia

Abstract

Qualitatively, soil texture is the consistency of a moist soil felt between the fingers and is associated with its quantitative aspect, i.e., the particle size distribution, which is determined in the laboratory. It is affected by the content and type of clay, silt and organic matter contents of the soil, and the ion composition on the clay fraction. The particle size distribution is generally plotted in a soil texture triangle, which delineates textural classes, and the names of these classes are correlated with the field texture descriptions. Texture is a fundamental property that determines the specific surface area of the soil, which in turn affects many of the physical and chemical properties and behavior of the soil, such as the soil water- and nutrient-holding capacities, soil hydraulic conductivity, soil consistency, resistance to cultivation, and hardsetting properties. Soil texture (sand or clay content) is generally one of the first properties used in developing pedotransfer functions for soil water characteristic properties.

INTRODUCTION

Besides color, one of the principal descriptors of a mineral soil (i.e., one with less than 10% organic matter content) is its texture, which is well correlated with the particle size distribution of the fine earth fraction (<2 mm fraction). The distribution of particle size is conveniently partitioned by particle size analysis (PSA) into subfractions of sand, silt, and clay, the proportions of which will have a dominant influence on many of the practical soil properties important to agriculture, the environment, and engineering purposes, such as ease of cultivation, nutrient- and water-holding capacities, water transmission characteristics, suitability for earth dam construction, and susceptibility to erosion.

PARTICLE SIZE DISTRIBUTION

With respect to particle size ranges, the subdivision into sand, silt, and clay fractions varies with country and professional institution.^[1] Examples of four of these particle size classifications are shown in Fig. 1.^[2] In defining soil texture, the first three systems are the most widely used in textural class designation. For describing a soil and/or soil horizon portion of a soil profile, the soil is allocated to a textural class. The textural class descriptors provide an indication of which particle size fraction is dominant, with the exception of a loam where no single size range exerts a

dominant influence. In the field, the textural class is estimated by the handfeel of a moist sample of fine earth fraction, when molded between the thumb and forefingers at just below the “sticky point.” In this moisture condition, the soil just begins to stick to the fingers, and its moisture content is approximately equivalent to field capacity or the amount of water retained at a water potential of -33 kPa.^[3] Because the process of hand molding destroys the structure of the soil, the estimate of the textural class will also be related to the particle size distribution. Initially, the soil is remolded several times to form a uniform moist bolus of about the size of a golf ball. Then, the bolus is deformed into threads^[4] (see Fig. 2) or ribbons of approximately 3-mm thick^[5] (see Fig. 3). The force necessary to deform and shear the bolus and the length of these threads or ribbons increase with clay content. At the same time, if the sample contains a particular size fraction that is readily identifiable by feel to the fingers, this is taken into account in deciding on the soil texture class, e.g., the grittiness of coarse sand or the slippery silky feel of silt. Alternatively, medium and coarse sand can also be seen with a hand lens, and fine sand can be heard by its crunchy grinding sound when remolding and shearing are done close to the ears. Finally, organic matter when present as humus at >10% usually confers cohesion to sandy textures and greasiness to clayey textures,^[6,7] which tend to make sandy and clayey soils feel more loamy in texture.

Taking all of the above description and criteria into account, soil texturing by hand is essentially a consistency

Fig. 1 The designation of particle size ranges from sand, silt, and clay by four professional institutions. The British Standards Institution and Massachusetts Institution of Technology used the same classification.
Source: From Brady.^[2]

test (see the entry *Consistence*, p. 471) at the sticky point.^[8] It then follows that since the amount of work and cohesion increase in the order of the three principal texture classes of sand, loam, and clay, they are often well correlated with the texture classes derived from PSA.^[1,9] Because additional criteria are used in describing the texture of a soil by hand, other than just particle size distribution per se, there are usually more classes derived from hand texturing than can be represented solely in terms of particle size distribution in a soil texture diagram.

PARTICLE SIZE ANALYSIS (PSA)

When accurate data on the soil’s particle size distribution are desired, a PSA can be conducted in the laboratory on a sample (25–50 g of oven-dry soil) of the fine earth fraction. The sample is treated to allow the individual primary soil particles to be freely suspended in water prior to the determination of the proportion of sand, silt, and clay. As primary soil particles are generally found as conglomerates or bonded aggregates, they are treated with one or more of the following sequence of treatments: boiling to soften the bonds, 30% hydrogen peroxide to oxidize organic matter bonds, and 1 M hydrochloric acid to dissolve silica and iron–aluminum bonds. This is then followed by the addition of sodium (Na) cations (as sodium hydroxide–Na hexa–metaphosphate mixture)

and mechanical shaking using a milk shaker or an end-over-end shaker (for 16 hours) to ensure that all clay particles are fully dispersed and remain dispersed. Alternatively, the ultrasonic probe is also routinely used to achieve effective separation of individual particles. Separation of the various size classes of particles is achieved using a combination of sieving, sedimentation, and decantation. Each size fraction is expressed as an oven-dry mass fraction or percentage of the original sample. Details of PSA methodologies can be found in a number of standard soils methodology texts.^[4,5,10] The percentage of sand, silt, and clay fractions are then plotted on a texture triangle that is appropriate for the size fractions selected. Some of the most frequently used texture triangles are shown in Fig. 4. The selection of texture diagram is dependent on the silt size fraction used.

SOIL PROPERTIES AFFECTING FIELD TEXTURE

Soil properties affecting the determination of field texture by hand^[1] are as follows:

- 1. Clay content (particles <0.002 mm in diameter)
- 2. The type of clay mineral (kaolinite, illite, or montmorillonite)
- 3. Silt content (particles between 0.002 and 0.02 mm in diameter)

Fig. 2 A guide to field assessment of texture for mineral soils in the United Kingdom by S. Northcliff, University of Reading, and J. R. Landon, Booker Agricultural International.

Source: From Loveland & Whalley.^[4]

4. Organic matter content
5. Oxides
6. Calcium and magnesium carbonate content
7. Cation composition
8. Strong, fine-textured aggregation

The details of their effects are given in the study by Hodgson,^[1] and the dominant effects of clay and silt particles are the reasons for why the final texture designation is based on PSA.

RELEVANCE OF SOIL TEXTURE

The most fundamental property associated with particle size distribution is the specific surface area (SSA) of the soil expressed as surface area per unit mass or $\text{m}^2 \text{g}^{-1}$ (see the entry *Surface Area: Specific*, p. 2255). Smaller particles possess larger SSA; for example, SSA for sand is approximately $0.01\text{--}0.1 \text{ m}^2 \text{g}^{-1}$, for silt, it is approximately $1 \text{ m}^2 \text{g}^{-1}$, and for clay, it may range from 10 to $800 \text{ m}^2 \text{g}^{-1}$. As most soils contain a considerable amount

Field Texture Groups	Ribbon length (mm)	Coherence of the bolus at sticky point	Feel	Other features	Texture Grade (Synonymous with Texture class)	Approx Clay (%)
1 <i>The Sands</i>	Nil	Nil	Sandy	Single sand grains adhere to fingers	1. Sand (S)	Commonly <5
	5	Slight	Sandy	Discolors fingers with an organic stain	2. Loamy Sand (LS)	5–10
	5–15	Slight	Sticky	Sand grains sticks to fingers and discolors with a clay stain	3. Clayey Sand (CS)	5–10

Source: From McDonald, Isbell, et al.^[5]

of clay, it is characterized by large SSA. All physical and chemical processes in the soil occur at the interface of the soil solids; hence, the larger the SSA, the greater the cumulative effect will be of these processes, and therefore the clay fraction plays the major role in this regard. Clays are referred to as the active fraction of the soil, whereas sand and silt are referred to as the skeleton of the soil.

Soil Consistency, Ease of Cultivation, and Soil Workability

Soil consistency is the deformation as a response of the soil to an externally applied force (see the entry *Consistence*,

p. 471) and is strongly affected by texture and water content. Moving from a high to low water content on a particular soil, the soil changes from a liquid to a plastic, semisolid, and solid phase. Each phase responds differently to an applied force, and the transitions are characterized by the Atterberg limits; these are the liquid, plastic, and shrinkage limits, which are all strongly dependent on the soil texture, specifically the clay content. The liquid and plastic limits are important engineering parameters of clayey, silty, and loamy soils that have to carry loads such as building foundation. From the agricultural perspective, the plastic phase of the soil should be avoided during cultivation, as the soil in this phase is highly compactible. The semisolid

Fig. 4 Three of the most frequently used texture triangles. The International Soil Science Society is based on particle size of sand (2–0.02 mm), silt (0.02–0.002 mm), and clay (<0.002 mm). The U.S. Department of Agriculture (USDA) triangle is based on silt fractions of 0.05–0.002 mm and the UK triangle on silt fractions of 0.06–0.002 mm.

Source: From Klute,^[10] Gee & Bauder,^[11] Rowell,^[12] and Hillel.^[13]

phase is the most suitable for cultivation and within this phase is an optimal water content for cultivation or the soil's workability. The range of water content that defines the semisolid phase and the soil's workability is dependent on the soil's texture and modified by the soil structure.

The ease of cultivation for soils of different textures gives rise to the expressions of "light-textured soils" and "heavy-textured soils" being used for sandy and clayey soils, respectively. Coarse-grained, sandy soils tend to be loose, well aerated, and easy or light to cultivate. Fine-textured soils tend to absorb much water and may become plastic and sticky when wet. Hence, they require much more energy and are heavy to cultivate. Upon drying, they tend to become dense and hard.^[14]

Nutrient- and Water-Holding Capacities and Transmission Properties

The SSA and the magnitude of the electrical charges per unit area of clay and silt determine the cation exchange capacity (CEC) of the soil, which is the amount of cations that a unit mass of soil can hold (see the entry CEC, p. XXXX). The larger the SSA, the larger is the soil's nutrient-holding capacity, e.g., CEC for kaolinite, illite, and montmorillonite clays range from 3 to 15, 10 to 40, and 60 to 120 mmol/kg, respectively. However, fine particle size distribution is generally associated with

lower infiltration and drainage rates. Therefore, sandy soils tend to have higher infiltration rates and generally experienced greater leaching, resulting in acid pH and low base saturation. On the other hand, clayey soils tend to have lower infiltration rates and less leaching, resulting in neutral to alkaline pH and high base saturation.

Particle size distribution and SSA are important determinants of the soil's water-holding capacity. Water is adsorbed on soil surfaces, and water will accumulate in the pore space between the particles as capillary water, which is held in the soil by the force exerted by the water menisci across the pores between particles. This force is inversely proportional to the size of the pore; hence, water is readily removed or drained from the larger pores. At field capacity, which is the water content of an undisturbed soil at a water potential of –10 kPa, sandy soils tend to have lower water contents than clayey soils. Similarly, at the wilting point, which is the water content where water is adsorbed onto soil surfaces by a force of –1.5 MPa, sandy soils have lower water contents than clayey soils. However, the plant-available water capacity (PAWC), or the amount of water held between field capacity and wilting point, is also lower in sandy soils. The approximate relationship between PAWC and texture is shown in Fig. 5.^[15] As water at wilting point is adsorbed on the surface of soil particles, it is predominantly affected by the particle size distribution or texture

Fig. 5 Approximate water-holding capacities of different textured soils.

Source: From Foth.^[15]

class. However, water at field capacity is accumulated in pore spaces and is capillary water. The latter is strongly affected by soil structure; this effect increases in surface area and clay content. Where the soil is poorly structured or finely structured, field capacity tends to be highly associated with the predominance of fine pores such as the black earths (Curve B in Fig. 5), whereas strongly structured soils have a predominance of large pores, field capacity tends to be lower for the same clay content such as the red Latosols (Curve A in Fig. 5). Particle size distribution will affect the pore size distribution of a soil, and, consequently, it will influence the soil's transmission characteristic, which is termed the soil's hydraulic conductivity K (see the entry *Hydraulic Conductivity*, p. 1133). As measurements of K are resource intensive and expensive, pedotransfer functions are generally used to estimate K and soil texture generally featured as the first factor considered in the development of suitable pedotransfer functions.^[16]

Packing of Particles—Hardsetting Characteristic of Soils

Particle size distribution also affects the potential packing density of the soil or soil aggregates.^[17–19] The presence of sufficient quantities of small particles that will fill the space between the larger particles will result in a massive structureless soil. This generally occurs on soils with 30–35% sand content. One specific soil characteristic associated with the presence of silt and fine sand particles (silty or fine sandy-textured soils) is hardsetting, which is a soil characteristic where the aggregates readily break down upon wetting. The structure will not be reformed, and the soil dries out rapidly into a hard consistency. It softens considerably upon rewetting.^[20] Hardsetting soils are characterized by low water-holding capacities, and they alternate rapidly

between soft and hard consistencies, often resulting in poor soil physical conditions for most plants. Such soils are sometimes referred to locally as “Sunday soils,” which are too wet to cultivate on Saturday and too hard on Monday with Sunday the only timeslot for cultivation.

CONCLUSION

Qualitatively, soil texture is the consistency of a moist soil felt between the fingers and is associated with its quantitative aspect, i.e., the particle size distribution. It is affected by the content and type of clay, silt and organic matter contents of the soil, and the ion composition on the clay fraction. Texture is a fundamental property that determines the SSA of the soil, which in turn affects many of the physical and chemical properties and behavior of the soil, such as the soil water- and nutrient-holding capacities, soil hydraulic conductivity, soil consistency, resistance to cultivation, and hardsetting properties.

Peatlands

Dale H. Vitt

Department of Plant Biology and Center for Ecology, Southern Illinois University, Carbondale, Illinois, U.S.A.

Paul Short

Canadian Sphagnum Peat Moss Association, St. Albert, Alberta, Canada

Abstract

Peatlands occupy only 3% of the global terrestrial surface, but hold 10% of the world's drinking water, and contain stored in peat about one-third of the earth's soil carbon (about equal to the total carbon dioxide in the atmosphere) and 9–16% of the world's soil nitrogen. Peatlands act as watershed filters and serve as habitat for a number of unique suites of animal species. Fungi are common and abundant, and insects are diverse, but little studied. Plant diversity is low but includes a number of rare and uncommon species. Peat has long been used as a soil amendment, and the harvesting of peat moss is a small, but important, industry where peatlands are abundant. The leading producer of commercial peat moss is Canada, and the industry maintains a view of responsible environmental management that strives to restore peatlands to their before-harvest condition. Additionally, peatlands are managed for enhanced tree growth through drainage and fertilization in some countries, and peat is harvested for electrical generation in a few northern countries. Peatlands contain a large, unstable stockpile of carbon that is sensitive to both climatic and anthropogenic disturbances. These disturbances have the potential to change the long-term peatland carbon sink into a source of carbon to the atmosphere; thus, *Wise Use*, especially conservation, of our peatland resources should be a priority.

INTRODUCTION

Peatlands contain abundant natural resources and are ecosystems that over the long term have net primary production of organic matter exceeding losses from decomposition and export and at millennial timescales have large stores of carbon.^[1] As a result, peatlands develop a deep layer of organic soil, or peat, that is composed of at least 30%, but usually more than 90% organic matter. Deposits of peat accumulate in place, contain a historical record of community change over time, as well as serve as proxies for past environmental and climatic changes^[2] and in some places hold a record of past human activities on the site. These records indicate that nearly all peatlands have initiated and developed over the past 10,000–12,000 years and since the last glaciation. Globally, peatlands represent a major carbon stockpile, storing approximately one-third of the world's soil carbon (450 Pg; petagram = 1×10^{15} g) and about 10% of the global drinkable water, yet cover only 3% of the world's terrestrial area.^[3] As compared to ocean and lake sediments that also contain large reservoirs of stored carbon and are relatively unaffected by atmospheric processes, peatland ecosystems, and the carbon stored in the layers of peat, are extremely vulnerable to climate change and land use changes. Additionally, peatlands are a sink for nitrogen (N), and it has been estimated that boreal peatlands contain about 9–16% of the global pool of N.^[4]

While all peatlands are wetlands, not all wetlands are peatlands, and the need to distinguish the difference is important to the recognition and management of peatland resources. In general, non-peat-forming wetlands are either treed or shrubby (swamps) or without woody vegetation (marshes). Both swamps and marshes have fluctuating water levels and relatively high amounts of nutrient inputs; hence, organic matter produced in these systems decomposes rapidly, and peat formation is limited. Peatlands (sometimes called “mires” in Europe) are usually classified as either fens or bogs (Fig. 1), depending on the source of the water. Fens receive waters from precipitation as well as from the surrounding uplands (i.e., geogenous water source), whereas bogs are somewhat raised above the surrounding area and receive water only from precipitation (i.e., ombrogenous). The ionic quality of these incoming waters greatly influences the structure and functioning of the ecosystem and dictates the amount and type of peat produced. Bogs and poor fens are dominated by the moss genus *Sphagnum* (Fig. 2), and it has been estimated that there is more carbon stored in *Sphagnum* than in any other plant genus, whereas rich fens have ground layers dominated by true mosses.^[5]

Peatlands are estimated to have originally occupied 4,258,000 km², of which about 74% are in non-tropical parts of the world. North America has 46%, Asia 35%, Europe 13%, South America 4%, Africa 1%, and Australia

Fig. 1 Right side: A poor fen in the foreground and treed bog in the background. The fen dominated by sedges and *Sphagnum*. Left side: Continental bog of Western Canada characterized by a dense tree layer of *P. mariana*.

and Antarctica less than 1%. Peatlands are concentrated in the boreal and arctic regions of the world where precipitation exceeds potential evapotranspiration. Countries with more than 50,000 km² of peatland are Russia (1,410,000 km²), Canada (1,235,000 km²), the United States (625,000 km²), Indonesia (270,000 km²), Finland (96,000 km²),

Sweden (70,000 km²), and Peru (50,000 km²). Loss of natural peatlands to anthropogenic disturbance is variable and ranges from 52% of the natural peatlands being lost in Europe and 50% in non-tropical Africa, 20% in non-tropical South America, 8% in non-tropical Asia, and 5% in North America. About 16% of non-tropical peatlands have been lost to disturbance, with agriculture accounting for 50%, forestry 30%, peat extraction 10%, and the remainder from urbanization, inundation, and erosion. Restoration efforts, especially in peat harvested bogs of North America, have been developed to return some of these areas to functioning peatlands.^[6]

SENSITIVITY TO DISTURBANCE

The large reservoirs of carbon and N found in peatlands have developed relatively over the past 10,000–12,000 years. Over this period of time, it is estimated that peatlands accumulated carbon at a rate of about 17–20 g m⁻² yr⁻¹ and that globally peat accumulation is about 40–70 Tg C yr⁻¹ (teragram = 1 × 10¹² g). As a natural resource, peatlands are subject to both anthropogenic and natural disturbance impacts. In North America, particularly in the Western Canadian provinces, wildfires account annually for the largest emissions of carbon, estimated at 6300 Gg C yr⁻¹ (gigagram = 1 × 10⁹ g), while anthropogenic impacts that include flooding from hydroelectric construction (–100 Gg C yr⁻¹), peat harvesting (–140 Gg C yr⁻¹), and mining (–50 Gg C yr⁻¹) account for –290 Gg C yr⁻¹. Considering that these Western Canadian peatlands sequester ±8940 Gg C yr⁻¹ and the results of permafrost melting contribute +160 Gg C yr⁻¹, the net estimate of annual carbon sequestration is +1320 Gg C yr⁻¹.^[7]

Globally, the conversion of peatlands to agriculture and forestry is estimated to contribute 100–200 Tg of C yr⁻¹ to the atmosphere, and this combined with global peat extraction of approximately 15 Tg of C yr⁻¹ would account for peatlands at the global scale to be a source rather than a sink for carbon.^[8] However, these estimates are rapidly changing, with changes in forestry practices along with regional differences in anthropogenic activities and the application of appropriate responsible peatland management practices.

NATURAL RESOURCES OF PEATLANDS

Although peatlands have often been considered as wasteland, even cancers on the landscape (illustrated in *The Lord of the Rings*, “Meres of Dead Faces” NW of Mordor), they actually contain a wealth of natural resources and perhaps more importantly carry out valuable ecosystem functions on the landscape. This view of peatlands as wastelands is exemplified by their use as prisons (e.g., the Gulags of the former Soviet Union and the German concentration camps such as Dachau), their use as landfills, and their use as

military training grounds, with the latter allowing some peatlands to be preserved in areas of concentrated human occupation (such as Western Europe).

Given the poor regard for these natural peatland resources, responsible peatland management has been a challenge. The *Wise Use of Mires and Peatlands*, published in 2002,^[7] provided an excellent framework for decision-making when considering the use of peatlands. The *Strategy for Responsible Peatland Management*, published by the International Peat Society in 2011,^[9] has provided a comprehensive management construct for peatlands worldwide. It provides those involved in or responsible for peatland management with strategic objectives and actions for implementation that for the first time defines objectives and actions for the conservation, management, and rehabilitation of peatlands globally, based on the principles of *Wise Use of Mires and Peatlands*. According to the *Strategy for Responsible Peatland Management*, peatland management includes organizing, controlling, regulating, and utilizing peatland and peat for specific purposes, which should be appropriate to the peatland type and use while respecting cultural, environmental, and socioeconomic conditions. The *Strategy for Responsible Peatland Management* is applicable to all types of peatlands under every use, including non-use, and it is directed to everyone responsible for or involved in the management of peatlands, or in the peat supply chain.

Water Resources

In areas where large portions of watersheds are covered by peatlands, these ecosystems provide important source areas for drinking water. For example, in Yorkshire, Britain, 45% of the public supply of water is from watersheds draining peatlands. Haworth Moor of *Wuthering Heights* fame was owned by a company providing drinking water. In the Northern Andes, peatlands are source areas for drinking water for millions of people living in the large cities of Colombia and Peru. In Western Canada's boreal forest, lake chemistry and functions are influenced by watersheds having large cover of peatlands. These peatland-dominated watersheds provide filtered waters to the downstream lakes and in some cases acidifying the lakes.^[10] The nutrient chemistry of these lakes is significantly different from lakes with only upland inputs.^[11] Thus, peatlands can provide a modifying influence on downstream ecosystems. The large dissolved organic carbon (DOC) component of peatlands, especially bogs, colors downstream lakes and streams. With warming and/or drying climatic conditions, coupled with the increased atmospheric deposition and pasturing of animals, bogs can degrade releasing large amounts of DOC to downstream drainages. This is a loss of carbon from the long-term store found in these peatlands. This loss from agricultural uses has been reported as significant in the British Isles.

Soil Resources

Peat has been extracted from peatlands for centuries for a number of uses, foremost of which is an organic substrate in agriculture and gardening. Its uses include biodegradable pots for the cultivation of seedlings, soil amendments for gardens, and growing media for both professional and amateur flower and vegetable growers. It also has been used as a substrate for mushroom growers and for tree nurseries. Among its unique properties for use as a soil amendment and as a growing medium are: 1) excellent water-holding capacity—holding up to 20 times its weight in water and retaining water for exceptionally long periods of time; 2) a low pH that functions to reduce the microbial activity, thus lessening the number of pathogens; and 3) lowering the rate of decomposition, and as a result, the amendment remains in the soil medium longer. Additionally, peat is easy to harvest (Fig. 3), handle, and ship to market. Peat harvesting is a small, but important, industry in Canada ($10.3 \times 10^6 \text{ m}^3$ harvested in 1999) and Germany ($9.5 \times 10^6 \text{ m}^3$ in 1999).

In Canada, the horticultural peat industry is well-established, although it is a relatively recent commercial industrial use of peatlands. Peat for energy was the initial focus of peat use in Canada, but there is no industrial use of peat for energy production. Since the postwar era, horticultural peat has become a major resource industry in rural areas of Canada, particularly in Québec and the Maritime Province of New Brunswick. Western Canada's Prairie Provinces (Alberta, Saskatchewan, and Manitoba) are areas of expansion for the industry and account for approximately 40% of the national production. The Canadian production principally services the horticultural industry of both Canada and the United States.

The Canadian industry, through policy and practice, is committed to the return of postharvest sites to functioning peatland ecosystems. Recognized throughout the world as leaders in the restoration of peatlands is the Industrial Chair for Peatland Management and the Peatland Ecology

Fig. 3 Vacuum harvesting of a drained peat field in Québec, Canada.

Research Group at the Laval University in Laval, Québec. Beyond the applied level of peatland restoration, the industry continues to actively promote responsible management of peatland resources throughout the provincial and federal agencies accountable for natural resource management. Peatlands (bogs and fens) need to be acknowledged as natural biological resources and managed to ensure that their environmental, social, and economic values are sustained. The key is responsible management that sets aside areas for protection and conservation and puts in place management practices that ensure the retention of ecosystem goods and services following development. The peat-harvesting industry has a commitment to support the continued leading-edge peatland research, application of science-based restoration techniques, and improved responsible peatland management in order to provide sustainable peatland management that recognizes the environmental, social, and economic values of peatland resources.

Historically, peat has also been used in a number of fascinating ways. During the 1800s and early 1900s, peat was used as litter in horse stables, especially for cavalry, railways, and transportation companies that stabled a large numbers of horses. In fact, this use led to the rapid development of peat extraction in Western Europe. It has been estimated that one French army with a 13,500-horse cavalry needed 22,000 tons of peat in one year.^[8] *Sphagnum* peat was used extensively during the Napoleonic and the Franco-Prussian Wars, by the Japanese in the 1904–1905 war with Russia, and in World War I by both sides as a substitute for cotton in surgical dressings. In Britain, “War Work for Women” included collecting and processing *Sphagnum* in the extensive British open bogs. Aboriginal people in North America used *Sphagnum* moss for diapers, and in the 1980s, *Sphagnum* was used in the commercial production of feminine hygiene products. Peat also forms a component of filtering systems for water purification. The cation exchange properties of *Sphagnum* allow the exchange of hydrogen ions for all base cations, including cationic forms of heavy metals. The absorbent properties of peat allow the absorption of large quantities of water, but when dried to less than 8% moisture, peat becomes hydrophobic and absorbs large quantities of petroleum products; as such, it has been used in oil spill cleanup and as floor mats in industries with petroleum spillage. The use of peat for building and insulation was widespread in Europe in the past. In Ireland, canal banks were lined with peat; in Finland, it was used as a liner for roadways; and in Russia and Belarus, it was pressed into sheets and used as insulation in buildings and industry.

Peat is also utilized for energy production. The use of peat for electrical generation is an important national strategic use of peat in Ireland, Finland, and Sweden. Within the Nordic countries of the European Union, the energy generation of peat is one of the most important uses of peat and will almost certainly remain important for countries with large peat reserves and in producing energy for

isolated locations. The use of peat briquettes for burning in household stoves, furnaces, and fireplaces is also common in rural Ireland, but peat is mixed with *Miscanthus* biomass to form more energy-efficient renewable products. Bord na Móna reports that overall about 4 megatons (=4 Tg) of peat are burned for energy generation each year, of which 1 megaton (=1 Tg) is used for local burning in households.

Biotic Resources

Since the early 1800s, and originating in Germany, peat has been used in balneology (baths). It is reported that owing to the biologically active substances in peat, such as humic acids, peat may influence the immune system and is effective against microorganisms. Peat is an important component in the distillation of Scotch whiskey. The special peaty flavor of Scotch whiskey is imparted by slowly drying the “green malt” over a smoldering peat fire.

Fens have long been cut for hay in both Canada and Eurasia. This “slough hay” is used for both fodder and straw for domestic animals. Also, drier peatlands have been long used as pasture. Wild plants are actively collected and eaten by local and indigenous people across the boreal zone. Cranberries (*Vaccinium oxycoccos* and *Vaccinium macrocarpon*) are commercially grown and processed for a number of juice products in Eastern United States and Canada. In Fennoscandia and Québec, Canada, the berries of cloudberry (*Rubus chamaemorus*; Fig. 2) and lingonberry (*Vaccinium vitis-idaea*; Fig. 4) are distilled for liquors, as well as used in preserves and jellies. A large number of medicinal preparations are produced from sundews (*Drosera* spp.). First Nations peoples of Canada used plants from peatlands extensively for both food and

medicinal preparations; e.g., leaves of *Ledum groenlandicum* (Labrador tea; Fig. 5) were boiled and drank for nausea.^[5]

Drainage of peatlands to improve forest growth has long been practiced in Fennoscandia, Great Britain, and Russia. The estimates are that 15×10^5 ha of northern peatlands have been drained for forestry use. In oceanic areas where peatlands are treeless, often non-indigenous tree species have been planted with subsequent fertilization, whereas in more continental areas that have stunted trees growing directly on the peat, the soils have been enhanced with drainage and fertilization. These practices, common in Europe and Asia, have not been implemented in any large scale in North America; however, black spruce (*Picea mariana*) is harvested from natural peatlands in Eastern Canada.

Biodiversity

Peatlands are among the last large undisturbed ecosystems in the world and serve as habitat for many animals and birds. Although there are no vertebrate species that occur exclusively in peatlands, peatlands do serve as primary habitat for Caribou in North America, especially bogs with an abundance of reindeer lichens (mainly *Cladonia mitis*; see Fig. 3). Both moose and black bear utilize peatlands for food and shelter. In northern areas, peatland specialists include the Arctic shrew, northern bog lemming, and southern bog lemming. Birds also occupy peatlands, but few are exclusive to these areas. Sandhill cranes nest in fens in Western Canada; American bittern, Wilson's snipe, and upland sandpipers also use peatlands as major habitats in Eastern Canada. Beavers, both in Europe and North America, may disturb peatlands, but the lack of suitable substrate and food resources limits their activities to the edges. Surprisingly, little is known about the

apparent rich invertebrate fauna of peatlands, where many undescribed species may occur. In the few studies completed, the invertebrate diversity is extremely high, yet little studied. In comparison, such environmental indicators as testate amoebae have been well studied and have been extensively utilized in studies that reconstruct past environmental conditions of the local area.^[12]

Carbon Resources

Over the long term, peatlands extract large amounts of carbon dioxide (CO₂) from the atmosphere and store it in deposits of peat. Peatlands have stored about the same amount of carbon as there is in the atmosphere. Some believe that carbon extracted from the atmosphere by peatlands during the interglacials reduced atmospheric CO₂ concentrations and resulted in the development of the glacial periods. There is some evidence that global CO₂ concentrations are coupled to peatland initiation and global climate.^[13] Although pristine peatlands have served as a sink for atmospheric CO₂, peatlands are a source for methane [a potent greenhouse gas (GHG)] and also for nitrous oxides. Wetlands, rice paddies, and animal livestock dominate global methane production, and emissions from peatlands are variable, but of less importance. While bogs produce little or no methane, fens may provide a rich source. Methane is a product of anaerobic decomposition and is often the highest in wet habitats with relatively high rates of organic matter turnover (such as rich fens and eutrophic marshes). Nitrous oxide emissions from pristine peatlands are low.

Net GHGs from the horticultural peat harvesting process reveal that the entire life cycle of peat extraction emitted 0.54 Gg of CO₂ in 1999 rising to 0.89 Gg CO₂ in 2000. Seventy-one percent of the emissions were associated with peat decomposition, 15% from land use change, 10% from transportation to market, and 4% from processing.^[14] Canadian peat horticultural emissions from all sources (0.89 Gg) represent 0.03% of all degraded peatlands (3 Pg) worldwide. Emissions are 0.006% of all total global net anthropogenic emissions (15.7 Pg). Within the Canadian context (given that the national total GHG in Canada at 771 Pg CO₂ in 2006), the peat industry represented 0.1% of total GHGs. Environmental Life Cycle Analysis, such as this, has led both the Canadian Sphagnum Peat Moss Association and European Peat and Growing Medium Association to recognize that peat harvesting is a significant source of carbon emissions, and peat harvesting companies are examining their emissions' footprint base and identifying opportunities to reduce their impacts.

PEATLAND RESTORATION

Following peat harvest, peat fields are bare and without vegetation. Decomposing peat produces GHGs, and these

areas provide little in the form of suitable habitat or ecosystem services. Beginning in the late 1990s, however, techniques were developed (mainly in Eastern Canada) to restore a viable living vegetative cover. Using the moss transfer technique developed through the research program at Laval University's Peatland Ecology Group, a *Sphagnum*-dominated plant cover has been reestablished within 3–5 years following restoration procedures, with biodiversity and hydrology approaching preharvest conditions. It is predicted that carbon sequestration should become a net sink within 15–20 years.^[6]

Forestry practices result in a steady decrease in the carbon store due to increased aerobic conditions in the upper peat profile, leading to increased decomposition. Even though greater initial tree growth of drained peatlands may increase carbon storage and exceed the losses from peat decomposition, longer-term cumulative losses from the peat result in an increase in carbon emissions to the atmosphere.^[15]

CONCLUSION

Peatlands occupy about 3% of the terrestrial surface of the world. These ecosystems are characterized by organic soils that contain about one-third of the world's soil carbon—about equal to the CO₂ in the atmosphere. This carbon store has accumulated gradually over the past 10,000–12,000 years and is extremely sensitive to land use changes and climatic change. Peatlands function as habitats for animals and provide valuable ecosystem services such as water storage and filtration. A variety of plant species that serve as food and medicine for local as well as aboriginal people are abundant in peatlands. *Sphagnum* moss has been used in a variety of commercial applications. Peat has been harvested for horticultural purposes and is a valuable soil amendment, and peatlands have been drained for agricultural and forestry practices, releasing CO₂ to the atmosphere, but the restoration of harvested peatlands provides a successful avenue for future sustainable management of this valuable resource.

Pedological Modeling

Ronald G. Amundson

College of Natural Resources, University of California—Berkeley, Berkeley, California, U.S.A.

Abstract

While models are powerful means of testing hypotheses and synthesizing contemporary knowledge in a concise way, models of all types are simplified, incomplete, mathematical descriptions of the “real” world. Increasingly, it is emphasized that models can never be fully verified. Experience shows that multiple models (or versions of the same model) may faithfully mimic empirical observations of interest, a dilemma illustrating a practical verification problem. In addition, mathematical models may be internally correct, but they may poorly represent the phenomena they intend to describe because of incomplete knowledge of the system and, as a result, incorrect assumptions. The truly unique role for pedologists, in addition to applying mathematics on their own, is to provide the unique conceptual foundation peculiar to soils—one informed by extensive field observations guided by ideas generated during previous modeling attempts—that will make pedological models relevant to scientists and society.

INTRODUCTION

“The fascinating impressiveness of rigorous mathematical analysis, with its atmosphere of precision and elegance, should not blind us to the defects of the premise that condition the whole process” by T. C. Chamberlin,^[1] commenting on Lord Kelvin’s (ultimately incorrect) calculation of the age of the Earth.

In pedology, and in other sciences, “models” are increasingly used as tools for understanding natural phenomena. But what is a model, how are models used in pedology, and how are models developed and modified?

OVERVIEW

To begin, the term “model” has been used interchangeably in pedology with other concepts, sometimes leading to confusion or miscommunication. In simple terms, a “model” has been described by some as “a form of highly complex scientific hypothesis,”^[2] i.e., “a simplified and idealized description or conception of a particular system, situation, or process (often in mathematical terms) that is put forward as a basis for calculations, predictions, or further investigation.”^[3] As briefly outlined below, the mathematical approaches to describe a phenomenon can be varied, but all must rest on a solid understanding of the soil, and the factors and processes, which affect it. This empirical knowledge in turn constrains the “assumptions,” which underlie any mathematical model development. A model based on an incorrect, or poorly developed, understanding of a soil and the

processes that affect it will likely be unable to describe the processes of interest, but that inability may in turn inspire the modeler to better understand the soil. Therefore, modeling can help refocus attention to fieldwork and to the type of data to be collected. A specific example of how assumptions affect the development of a model is given later in this entry.

The first step in modeling soils—or anything—is to define the object of interest. In applying models to pedology, it should be recognized that soil is, in reality, a continuum of objects distributed across the earth’s surface—both in space and in time. The exact lateral boundary between one “soil” and another, or the vertical boundary between soil and non-soil, is arguably impossible to determine. Jenny^[4] first applied principles derived from the physical sciences to the conceptualization and modeling of soils. Jenny’s approach was to divide the continuum of soils on the earth’s surface into “systems,” which are arbitrarily defined, discrete, 3-D segments of the landscape that are amenable to mass or energy budgeting. The volume of these systems (both the chosen area and depth) is arbitrary, but it sets the stage for the mathematical formulations that are chosen to represent or describe it. A second important aspect of soils is the vast amount of time, and the array of unknown processes, that may have affected any soil system. This complex history in turn forces pedologists to develop tools, concepts, and modes of enquiry not always confronted by their experimental colleagues. Finally, soil formation is the result of an incompletely understood array of processes, and pedological models invariably are attempts to mathematically capture one, or at the most, a very restricted subset of the full suite of biogeochemical processes that affect a soil system.

In the pedological literature, more attention has possibly been devoted to classifying and discussing models^[5] than actually developing them. Unfortunately, much discussion has focused on the “pros and cons” of the *Factors of Soil Formation: A System of Quantitative Pedology*^[4] in the realm of pedological models. Briefly, the factorial “model” discussed in a book-length treatise by Jenny^[4] can be symbolically represented as follows:

$$s = f(\text{cl}, \text{o}, \text{r}, \text{p}, \text{t}, \dots) \quad (1)$$

where s is the soil properties; cl , climate; o , biota; r , topography; p , parent material; and t , time.^[4,6] The general truthfulness of this statement is almost beyond dispute (virtually every pedologist would ultimately have to agree that soil forms in response to variations in these factors, and that soil properties can also be numerically correlated with variations in these factors). Indeed, soil is “defined” in terms of this statement:

Soil is the “collection of natural bodies occupying portions of the earth’s surface that support plants and that have properties due to the integrated effect of climate and living matter, acting upon parent material, as conditioned by relief, over periods of time.”^[7]

Based on this definition, it would be more correct to define the state factor “model,” or “theory” as it has been alternately called, as a pedological “law” given its universal truthfulness and common definitions of scientific laws.^[8] At the very least, it is a fundamental underlying theory of pedology in the sense of Kuhn.^[9] This definition would also allow the discussion of models in pedology to move beyond this fundamental truism (and a useful quantitative and mathematical tool in its own right) to the development of mathematical models, as they are commonly considered and used in geochemistry, geophysics, and related fields. The remainder of this entry deals with these more practical modeling issues.

MODELING PROCESSES

Typical approaches to mathematically modeling soil processes involve the development of a mass or energy balance model. The mathematics used will ultimately hinge upon one’s understanding of the soil properties, the processes that presumably control them, and how these processes may vary over time. Some of the simplest models may be analytical models with time-independent variables. Alternative modeling approaches may involve the abandonment of time invariant parameters and, ultimately, the incorporation of relatively random changes in the rate of the process and factors that affect it.

As an example, it began with possibly the first true mathematical model of a pedogenic process for this entry—a time-dependent, analytical, mass-balance model of O

horizon formation in forest soils developed by Jenny, Gessel, and Bingham.^[10] Jenny, Gessel, and Bingham^[10] defined the system of study, discussed the processes that affect it, and, for the simplest cases they considered (tropical forests with nearly constant litter inputs with time), described the change in O horizon mass (F , in mass per area) with time as follows:

$$dF = A dt - k(F + A) dt \quad (2)$$

where A is litter inputs (mass/area/time), and k , decomposition constant (1/time; Jenny, Gessel, and Bingham^[10] give a fuller discussion of calculation and definition of k). Upon integration, the solution to Eq. 2 provided by Jenny was as follows:

$$F = \frac{A(1 - k)}{k} (1 - e^{-kt}) \quad (3)$$

This model, as well as the permutations of it, has served as the foundation for decades of research and modeling of the soil organic carbon budget. The model has been extended for use in stable isotopic studies of soil organic matter^[11] and in modeling turnover times of soil organic carbon.^[12] However, the analytical model, as developed by Jenny, assumes constant inputs with time (a restriction that he noted does not occur in all situations) and constant decomposition rates with time. It also assumes that all organic matter is homogeneous (and by implication, has the same decomposition rates).

Work since the early 1990s in particular has revealed that soil organic matter (and even litter layers) can best be viewed as multiple pools of soil organic matter, each with their own characteristic input and decomposition rates. In simplest terms, multiple pool models of soil organic matter can be expressed as follows:

$$\frac{dC}{dt} = \sum_{i=1}^n (I_i - k_i C_i) \quad (4)$$

where C is the total mass of soil carbon (mass/volume); I_i , inputs of pool i (mass/volume/time); k_i , decomposition constant of pool i (1/time); and C_i , mass of soil carbon in pool i (mass/volume).^[11] Even these multiple pool models do not capture other aspects of soil formation, the variation in soil carbon with depth, and the likelihood that the process may have varied unpredictably over time. To address the first issue, models may include a downward transport term and depth-dependent inputs. For a single pool of organic matter, a basic depth-dependent model is as follows:

$$dC/dt = I - v \frac{\partial C}{\partial Z} - kC \quad (5)$$

where v is the advection coefficient (distance/time).^[11] Even these models can be made more complex, e.g., to include the process of diffusion.^[13]

Analytical solutions to all the aforementioned models require time invariant parameters. The inclusion of time-dependent parameters may be accomplished through numerical means. Yet, soils form over thousands to millions of years, with numerous unknown perturbations to the system that elude the fundamental framework of these simple models.^[14] It is these real-world complications imposed by nature that weaken the utility of relatively simple, time invariant, deterministic models. Phillips^[14] began the discussion of applying non-linear dynamical system theory to soil modeling, with the goal of explicitly incorporating the role that random differences in initial conditions and historical contingencies have on the processes of soil formation. Undoubtedly, work of this nature is one of the future challenges in the field of pedological modeling.

CONCLUSION

While models are powerful means of testing hypotheses and synthesizing contemporary knowledge in a concise way, the previous discussion serves to illustrate that models of all types are simplified, incomplete, mathematical descriptions of the “real” world. Increasingly, it is emphasized that models can never be fully verified (confirmed as the establishment of truth).^[2] Experience shows that multiple models (or versions of the same model) may faithfully mimic empirical observations of interest, a dilemma illustrating a practical verification problem. In addition, mathematical models may be internally correct, but they may poorly represent the phenomena they intend to describe because of incomplete knowledge of the system and, as a result, incorrect assumptions. Knowledge of the soil is essential in modeling, for as Baker^[15] has noted, “mathematics (is) the science that draws necessary conclusions without regard to facts.”

Given the ultimate simplicity and abstractness of models, and the ultimate complexity of nature in general, and soils in particular, the question “why model in the first place?” may be asked.^[2] Pedological processes are first-order controls on global atmospheric^[16] and aquatic chemistry, and even relatively simple analytical models of soil processes have thus far proven useful to link these global reservoirs. The truly unique role for pedologists, in addition to applying mathematics on their own, is to provide the unique conceptual foundation peculiar to soils—one informed by extensive field observations guided by ideas

generated during previous modeling attempts—that will make pedological models relevant to scientists and society.

Pedometrics

Alex B. McBratney

Budiman Minasny

Department of Environmental Sciences, University of Sydney, Sydney,
New South Wales, Australia

Abstract

Pedometrics is defined as the use of quantitative methods for the study of soil distribution, genesis, and sustainability. Pedometrics addresses soil science problems from the perspective of emerging approaches such as wavelet analysis, fuzzy set theory, etc. It also deals with utilizing modern analytical tools to quantify soil properties rapidly over space and time. Key areas of research include numerical soil classification, fuzzy sets, geostatistics, sampling, soil inference systems, and modeling pedogenesis.

INTRODUCTION

The term *pedometrics* was coined by McBratney in the late 1980s and is defined as the use of quantitative methods for the study of soil distribution, genesis, and sustainability. Pedometrics is a neologism derived from the Greek roots *pedos*, soil, and *metron*, measurement. Pedometrics is used analogously with other words such as *biometrics*, *psychometrics*, *econometrics*, *chemometrics*, and the oldest of all, *geometrics*.^[1] Pedometrics uses mathematical and statistical methods to deal with the variation in soil properties and processes over space and time. Pedometrics is also sometimes referred to as “soil science under uncertainty,” which addresses soil-related problems when there is uncertainty due to deterministic or stochastic variation, vagueness, and lack of knowledge of soil properties and processes.

A BRIEF HISTORY

Although the term *pedometrics* was coined in the 1980s and formally recognized as a different branch of soil science, pedometrics is not a new subject. Mathematical and statistical methods have been applied to soil studies since the late 19th century and early 20th century with applications in agronomy, soil survey, and soil physics.

For several decades of the 20th century, pedometrics (although not formalized and defined) was a tool for designing experiments and surveys and in advisory work. In the 1960s, pedometrics research was concerned with the problem of soil classification and applied the methods of numerical taxonomy. In the late 1970s, pedometricians began to treat soil properties as spatially correlated random processes and to utilize geostatistics for analysis and prediction. In the 1990s, pedometricians started to experiment with contemporary mathematical and statistical techniques

such as fuzzy sets, fractals, wavelets, and data-mining techniques for the description and prediction of soil properties. The application is largely focused on digital soil mapping to efficiently produce maps of soil properties. Pedometrics has also begun to attempt to elucidate pedogenesis by quantifying relations between individual soil properties and controlling factors.

Webster^[1] reviewed many early pedometric studies. The textbook by Webster and Oliver^[2] provided a concise, yet comprehensive introduction to geostatistics and its application in soil science. Grunwald^[3] presented and discussed pedometric techniques applied to soil-landscape modeling.

A bibliometric study of the composition of papers of the soil science journal *Geoderma*, from its inception in 1967 until 2001 (Fig. 1),^[4] showed that papers on pedometrics

Fig. 1 Trends in pedological subdisciplines and subjects reported in *Geoderma* between 1967 and 2001. The ordinate is the percentage of papers.

Source: From Hartemink, McBratney, et al.^[4]

have risen from less than 3% in 1967 to around 18% of all papers in 2000. It is the fastest growing research area in pedology.

KEY AREAS OF RESEARCH

Pedometrics addresses soil-related questions from a quantitative point of view. The need for the quantitative approach arises from a general demand for quantitative soil information in order to improve economic production and environmental management. There are several key areas of research in pedometrics, which attempt to understand the pattern of soil distribution in character space, soil spatial and temporal variation, the utility and quality of soil, and, ultimately, the genesis of soil.

Numerical and Continuous Classification

Pedometrics attempts to resolve some of the polemics of soil classification by a search for insight into the structure of soil character space. Pedometrics approaches soil classification problems by creating soil classes based on measurable soil information with objective statistical criteria. This began in the late 1950s, with the invention of the digital computer, which allowed the calculation of taxonomic distances between soil profiles. Similarities were calculated between soil profiles, represented as similarity and distance matrices, which allowed a representation of the multivariate data in a few dimensions. This is called ordination, by which a view of the soil property universe was first revealed.^[5,6] Numerical classifications can be created both hierarchically and non-hierarchically using various clustering algorithms.^[7]

Conventional methods of soil classification are based on the logical model of hierarchically arranged, mutually exclusive classes. Conventional methods imply that soil classes are discrete and discontinuous with sharp boundaries and can be represented by a central concept idea known as a typical profile. The intergrading nature of the soil population was recognized in a formal way using the concept of fuzzy sets. This allowed the creation of non-hierarchical continuous classes based on the fuzzy k-means algorithm.^[7] Each class is defined by a centroid or a list of average properties, and the membership of a soil individual to the classes is defined by the relative taxonomic distance between the soil individual and the centroid for each class. In addition to intergrades, extragrades were also recognized. This allowed for more continuous soil mapping, allowing a more natural approach when using geostatistical methods.

Fuzzy Sets

Soil phenomena are sometimes imprecisely defined, while soil scientists like to allocate soil attributes to discrete

classes. The fuzzy set theory is a means of dealing with inexact concepts. In a conventional set theory, objects are allowed to belong only to one set, whereas in fuzzy set theory, they may belong totally, partly, or not at all to a set. The fuzzy set theory is a generalization of the abstract set theory and stems from inexactness and uncertainty, as a result of insufficient data or partly defined classes. The main feature of fuzzy sets is the grouping of individuals into classes where boundaries are not, or cannot be, sharply defined. Fuzzy logic models soil data as memberships to classes, which can have gradual transition from one class to the others, as opposed to sharp boundaries in classical set theory.^[8] A review of the development and application of the fuzzy theory in soil science is given by McBratney and Odeh.^[9]

Geostatistics

Soil attributes vary spatially and temporally in a sometimes continuous, sometimes discrete, sometimes haphazard, fashion. Using the existing and conventional technologies, we can only measure most attributes of the soil at a finite number of places and times on relatively small volumes, and therefore, statements concerning the soil at other places or times involve estimation, prediction and, an inevitable uncertainty. One of the tasks of pedometrics is to quantify this variation so that it can be known and managed accordingly. Pedometrics seeks insight into such spatiotemporal patterns using geostatistical and other spatial and temporal description and prediction tools.

The basics of geostatistics is to be able to measure how soil varies in a field and predict its values at places where it is not measured. The underlying principle is treating soil attributes as random variables, assuming stationarity (some statistics of the random process are same everywhere in a field). The assumption is that the soil properties in a random field are spatially auto-correlated and can be modeled using a variogram. Using information on the variogram, soil properties can be predicted over the field using a technique called kriging (Fig. 2). There are variants of kriging to deal with non-normal distributions and changes in the mean and variance (non-stationarity) such as indicator kriging, universal kriging, and regression kriging. The detailed explanations of the theory and applications in soil science are given by Webster and Oliver^[2] and Goovaerts.^[10]

The more rigorous statistically based approaches for spatial prediction are the residual maximum likelihood approach and best linear unbiased prediction.^[11] The geostatistical model of spatial variation is a special case of the linear mixed model where the data are modeled as the additive combination of fixed effects (e.g., the unknown mean and coefficients of a trend model), random effects (the spatially dependent random variation), and independent random error (nugget variation in geostatistics).

The Bayesian maximum entropy approach was developed for spatial and temporal prediction as an alternative to

Fig. 2 Example of geostatistical prediction of subsoil pH. From field observations (A), spatial variability is characterized by a variogram (B). We can see that the pH values have a strong spatial correlation up to a separation distance of 600 m. The information on the soil variogram is used in a spatial prediction technique called kriging to produce a map of soil pH (C). Kriging provides the estimation of pH value at unknown location as a weighted average of the data in its neighborhood. The weights associated with neighboring observations depend on the way pH varies in space as described by the variogram. In addition to the estimate, kriging also calculates the uncertainty of the prediction (D).

kriging.^[12] It can take into account simultaneously data of various types and qualities. The data can be exact measurements, intervals of values, or probability density functions.

Soil Sampling

As soil varies across space and time, and under existing technology, it is impossible to capture the soil properties completely. The purpose of sampling is to obtain data that enable the estimation of some statistical parameters or spatial predictions of some properties over an area. Sampling is constrained by financial and available resources; thus, an efficient sampling strategy is sought for applications in soil survey for mapping and for establishing sites for monitoring networks. As an example, a good statistically based soil sampling scheme for estimating the mean nutrient concentration of fields can be used as a tool

for environmental regulation of the application rates of manure.^[13] Several sampling strategies have been developed in soil science, namely, for estimating the mean concentration of nutrient or contaminant in a field, for estimating a variogram, and for estimating variables within an area using spatial interpolation. This includes methods that minimize the kriging variance, provide an optimal spatial coverage, and establish a prediction model from secondary or ancillary variables. This topic is covered extensively by de Gruijter et al.^[13]

Soil Inference Systems

Soil analysis is expensive, and some functional properties such as available water capacity needed in many crop and environmental models are limited and not available in most areas. They need to be predicted from more other simple and

Fig. 3 Spectral soil inference system. Spectral calibration (left box) and an example of a soil inference system (right box). Spectral calibration involves the generation of prediction model called partial least squares regression (PLSR) to predict soil properties. Given a new spectrum, PLSR will predict the basic soil properties (clay, silt, sand, and organic C content) along with their uncertainties. These basic properties are then used to calculate other properties (bulk density), and the resulting input and model uncertainties are quantified. Further, basic properties and the predicted bulk density are used to calculate water content at field capacity and wilting point with subsequent available water capacity.

Source: From McBratney, Minasny, et al.^[16]

easy-to-measure properties. Soil inference systems take measurements with a given level of certainty and infer data that are not known with minimal uncertainties by means of logically linked predictive functions.^[14] These predictive functions are referred to as pedotransfer functions.^[15] The basic assumption underlying soil inference systems is that if we know or are able to predict the basic fundamental properties of the soil, we should be able to infer all other physical and chemical properties using pedotransfer functions.

Spectral soil inference systems, which combine prediction of soil properties from infrared spectroscopy and inference of soil properties using pedotransfer functions, were proposed by McBratney et al.^[16] as a means of predicting soil functional properties from a combination of various inputs, such as diffuse reflectance spectroscopy and basic soil properties (Fig. 3).

Modeling Soil Formation

Ultimately, pedometrics would attempt to provide a theory of soil variation through mechanistic models of soil evolution. This could be achieved by encapsulating knowledge of pedological processes in mathematical forms as an alternative to purely statistical approaches. The success of such a modeling approach will depend on pedological knowledge and the non-linearity of processes. The advantages of successful modeling of soil formation are substantial and

manifold. Soil spatial and temporal variation and soil genetic classes would be predictable from such a model. The first mechanistic soil profile model as a component of hillslope models was proposed by Kirkby.^[17] Initial work on modeling pedogenesis in the landscape has begun.^[18]

CONCLUSION

Pedometrics generally addresses the same issues as pedology but focuses on problems that can be formulated quantitatively and can be solved with mathematical and statistical techniques. Pedometrics is also closely related to other soil science subdisciplines: 1) soil physics; 2) chemistry; and 3) biology (Table 1). The following are the key areas of application:

1. Precision agriculture: This studies the spatial variation in crop yield and the soil and environmental factors that contribute to it. Pedometrics research has improved our understanding of the impact of spatial variability on crop yield and management and suggested differential treatments over a field.
2. Digital soil mapping: See the entry *Digital Soil Mapping* (p. 675).
3. Land evaluation: This is the process of predicting the potential use of land on the basis of its attributes.

Table 1 Pedometrics research in soil science subdisciplines.

Subdisciplines	Pedometrics research
Pedology	Modeling soil formation, numerical soil classification, spatial prediction of soil properties and soil classes, and chronofunctions
Soil survey	Soil sampling and digital soil mapping
Soil physics	Scaling, pedotransfer functions, uncertainty analysis, and time series analysis
Soil chemistry	Chemometrics and infrared spectroscopy for rapid analysis of soil properties
Soil biology	Quantifying soil biodiversity and spatial prediction of soil microbial diversity

A variety of analytical models can be used in these predictions, ranging from qualitative to quantitative, empirical to mechanistic, and specific to general.^[19]

- Contaminated sites: Pedometrics has been using geostatistical techniques to describe spatial distribution of heavy metals, pesticides, and salinity. These techniques provide estimates of concentration for an unvisited site and also the probability of the concentration at that location exceeding a critical threshold.^[10]

Pedotransfer Functions

J.H.M. Wösten

*Alterra Research Institute, Wageningen University and Research Center,
Wageningen, the Netherlands*

Abstract

Pedotransfer functions (PTFs) are a powerful tool in estimating physical, chemical, and fertility properties of soils. Because PTFs predict properties that are difficult to obtain from already available basic soil properties, they have the clear advantage that they are relatively inexpensive and easy to derive and to use. For application on a specific location, use of PTFs might not be appropriate. Most successful PTFs are developed from large and reliable databases. Accuracy and reliability of PTFs will be appropriate for many applications on a regional and national scale. The search for data mining tools to develop better, more flexible PTFs, and the search for additional soil properties, as inputs in PTFs are important directions for improving PTF accuracy and reliability. Uncertainty in PTFs can be quantified. Its effects on calculated functional aspects of soil behavior will help to assess if an input parameter needs further detailing, and decide which one to assess to arrive at more accurate results.

INTRODUCTION

Simulation models, which are indispensable tools in modeling water and solute movement into and through soil, require as key input parameters easily accessible and representative hydraulic characteristics. Techniques to measure these characteristics are relatively time-consuming and therefore costly. At the same time, good predictions of the characteristics instead of direct measurements may be accurate enough for many applications. Considering the desired accuracy and the available financial resources, it is rewarding to analyze existing databases containing measured hydraulic characteristics and to establish relationships that predict the characteristics from measured basic soil data. These predictive relationships are called “pedotransfer functions” (PTFs)^[1] and they essentially translate data “we have” into data “we need.” Basically, PTFs relate soil characteristics being assembled during soil survey to more complex characteristics needed for simulation. Predicting soil hydraulic characteristics dominates the research field, though soil chemical and soil biological characteristics are also being predicted. Several reviews on PTF development and use have been published.^[2,3]

Large databases on measured hydraulic characteristics, such as UNSODA,^[4] HYPRES,^[5] WISE,^[6] and United States Department of Agriculture Natural Resource Conservation Service pedon database,^[7] form the essential, basic sources of information for the derivation of PTFs. In using PTFs, insight is needed to determine the input variables that are to be included in a PTF, what technique

is to be used to establish a PTF, and how accuracy and reliability of PTFs are to be quantified.

FUNCTIONS USED TO DESCRIBE THE WATER RETENTION AND HYDRAULIC CONDUCTIVITY CHARACTERISTICS

Describing hydraulic characteristics as functions rather than as tables has the clear advantage that they can be easily incorporated in simulation models. There exists a wide range of different equations for the description of the characteristics. The following equations to describe volumetric soil water content, θ , and hydraulic conductivity, K , as functions of pressure head, h , are widely used:^[8]

$$\theta(h) = \theta_r + \frac{\theta_s - \theta_r}{(1 + |\alpha h|^n)^{1-1/n}} \quad (1)$$

$$K(h) = K_s \frac{[(1 + |\alpha h|^n)^{1-1/n} - |\alpha h|^{n-1}]^2}{(1 + |\alpha h|^n)^{(1-1/n)(l+2)}} \quad (2)$$

In these equations, the subscripts r and s refer to residual and saturated values, and θ , n , and l are parameters that determine the shape of the curve. The residual water content θ_r refers to the water content, where the gradient $d\theta/dh$ becomes zero ($h \rightarrow -\infty$). The parameter α (1/cm) approximately equals the inverse of the pressure head at the inflection point. The dimensionless parameter n reflects the steepness of the curve. The dimensionless parameter l

Fig. 1 Geometric mean water retention (A) and hydraulic conductivity (B) characteristic solid lines, standard deviations bars, and van Genuchten fits dotted lines for the texture class “medium fine topsoil.”

determines the slope of the hydraulic conductivity curve in the range of more negative values of h .

PTFs to predict the model parameters θ_r , θ_s , K_s , α , l , and n from basic soil data were built by many authors.^[9] Fig. 1 shows the mean water retention and hydraulic conductivity characteristics, also called class PTFs, for the texture class “medium fine topsoil.”^[5]

SELECTION OF PTF PREDICTOR VARIABLES

Soil properties affecting water retention and hydraulic conductivity are manifold.^[10] Table 1 lists the properties used most often as predictors because of their availability and because they proved to be the most promising ones.

Table 1 Soil properties often used in PTFs.

Particle size properties	Hydraulic characteristics	Morphological properties	Chemical/mineralogical properties	Mechanical properties
Sand, silt, clay	Water content at	Bulk density	Organic carbon	Penetration resistance
Fine sand	−33 kPa	Porosity	Organic matter	
	−1500 kPa	Horizon	CEC	
Very coarse sand, coarse fragments	Reference moisture retention curve	Structure	Clay type	
Median or geometric mean particle size		Grade	CaCO ₃	
		Size	Iron	
		Shape		
Water-stable aggregates		Color		
		Consistence		
		Pedality		
		Landscape position		

“Particle size distribution” is used in almost all PTFs. Particle size classes differ in different national and international classification systems, and so the number and the size of classes used in PTFs may also differ. Using sand, silt, and clay contents is a common approach.

“Limited, measured water retention data” at, for instance, two pressure heads may dramatically improve predictions of the complete water retention characteristic.

“Porosity or bulk density” is an important variable in many PTFs.

“Soil structure and morphology descriptors” such as the parameter topsoil and subsoil are successfully included in PTFs.

“Landscape position” is used as a topographic variable in PTFs.

“Organic matter content” is often used as predictor, but because bulk density and organic matter content are correlated, bulk density may effectively substitute organic matter content.

“Mechanical properties and shrink–swell parameters,” as characterized by the coefficient of linear extensibility, are used to estimate both water retention and K_s .

METHODS TO DEVELOP PTFs

When the set of PTF input parameters is defined and the PTF output is decided upon, a method is selected to relate input and output. The most prominent methods to create this relationship are discussed below.

Regression Analysis

The oldest and most widely used method to build PTFs was, exclusively, linear regressions, but this method is gradually being replaced by non-linear regression. An advantage of using regression techniques is that the essential predictor variables can be found automatically using stepwise regression. A drawback of regression is that it requires a model of the dependency of soil properties, which is almost impossible now that large digitized databases containing numerous soil properties are widely available. One remedial approach is to use principal component analysis. It allows identification of a small number of new variables that are linear combinations of the original predictors and that can explain a large percentage of variability within samples. An example of this type of PTF predicting the saturated water content θ_s is presented in Table 2.

Artificial Neural Networks

Artificial neural networks (ANNs) are becoming a common tool for modeling complex “input–output” dependencies. The advantage of ANNs is that no *a priori* model that relates input to output is required. After establishing the

Table 2 Continuous PTFs developed from the HYPRES database.

$$\begin{aligned}\theta_s = & 0.7919 + 0.001691C - 0.29619D - 0.000001491S^{2a} \\ & + 0.0000821OM^2 + 0.02427C^{-1} + 0.01113/S \\ & + 0.01472\ln(S) - 0.0000733OMC - 0.000619DC \\ & - 0.001183DOM - 0.0001664 \times \text{topsoil} \times S \\ & (R^2 = 76\%) \end{aligned}$$

^a θ_s is the saturated water content in the van Genuchten equations; C, percentage clay (i.e., percentage $<2 \mu\text{m}$); S, percentage silt (i.e., percentage between 2 and $50 \mu\text{m}$); OM, percentage organic matter; D, bulk density; topsoil and subsoil are qualitative variables having the value of 1 or 0; and $\ln$, natural logarithm.

network structure and finding coefficients to express the degree of influence of the network components on each other, an ANN generates a complex formula relating input with output values. This formula can be used like a regression formula. ANNs consisting of many interconnected simple computational elements, called nodes or neurons, are comparable to the best non-linear statistical regression approaches.

Group Method of Data Handling

The group method of data handling (GMDH) has, unlike ANNs, a built-in algorithm to retain only essential input variables in a flexible net of regression equations, which relates inputs to outputs. GMDH is a technique of finding an approximate relationship between a set of input variables $x_1, x_2, \dots, x_N$ and an output variable y . When the number of input variables is very large, or the relationship between inputs and output is very complex, GMDH successfully competes with statistical regression.

Regression Tree Algorithm

Regression tree algorithm is a recursive data partitioning algorithm that initially splits the data set into two subsets based on a single best predictor variable (the variable that minimizes the variance in the response). It then does the same on each of the subsets and so on recursively. The output is a tree with branches and terminal nodes. The predicted value at each terminal node is the average at that node.

Fig. 2 shows the accuracy of predicting water content at -33 kPa pressure head with the last three methods.

ACCURACY AND RELIABILITY OF PTFs

As empirical equations, PTFs are routinely evaluated in terms of the correspondence between measured and estimated values. When measured values are those used to develop the equation, the accuracy of the equation is

Fig. 2 One-to-one diagrams showing accuracy of predicting water content at -33 kPa suction with three methods: (A) back propagation ANN; (B) GMDH; and (C) regression tree algorithm. As can be seen, the accuracy of the three methods is quite comparable. In all three cases, the RMSE is around 3.4 vol%, the R^2 value of the regression is around 0.9 , the slope of the regression is close to one, and the intercept is about 0.001 vol%.

evaluated. When the measured values are different from the ones used to develop the equation, the reliability is evaluated. A multitude of statistics is used in PTF development including: multiple determination coefficient (R^2), root mean square error (RMSE), mean error (ME), and t-statistics to test the null hypothesis.

Accuracy of PTFs

Using the same statistics, the accuracy of existing PTFs varies appreciably. Accuracy estimates themselves may serve as benchmarks. However, they should be compared to variability of other measured input data. The model should not be more accurate than data used in the model development. Therefore, the PTF can be thought to be accurate if the variability of the PTF errors does not differ significantly from the variability in data, and if the average error does not significantly differ from zero.

Reliability of PTFs

The reliability of PTFs can be evaluated by cross-validation, i.e., splitting the available data set in a development and validation subset, or by using an independent data set.

Many studies assessed the reliability of PTFs by applying them to independent, regional data sets. From this, it appears that PTFs developed from regional databases give good results in regions with a similar soil and landscape history.

CONCLUSION

A number of conclusions can be formulated.

1. PTFs are a powerful tool in estimating physical, chemical, and fertility properties of soils. Because PTFs predict properties that are difficult to obtain from already available basic soil properties, they have the clear advantage that they are relatively inexpensive and easy to derive and to use.
2. For application on a specific location, use of PTFs might not be appropriate. In this case, direct measurement is the only option. PTFs should not be used to make predictions for soils that are outside the range of soils used to derive the PTFs. In other words, use of PTFs for interpolation purposes is safe but dangerous to use for extrapolation.
3. Most successful PTFs are developed from large and reliable databases. This implies that well structured and easily accessible national and international databases of measured soil hydraulic characteristics need to be created. PTFs should be periodically updated as more measured data become available from these databases.
4. Accuracy and reliability of PTFs will be appropriate for many applications on a regional and national scale. On these scales, temporal and spatial variability of other than hydraulic characteristics most likely will also have an important impact on the modeling results.
5. The search for data mining tools to develop better, more flexible PTFs, and the search for additional soil properties, as inputs in PTFs are important directions for improving PTF accuracy and reliability.
6. Uncertainty in PTFs can be quantified. Its effects on calculated functional aspects of soil behavior will help to assess, if an input parameter needs further detailing, and decide which one to assess, to arrive at more accurate results.

Permafrost: Soil Temperature and Special Problems

Douglas Kane

Julia Boike

Water and Environmental Research Center, University of Alaska, Fairbanks, Alaska, U.S.A.

Abstract

Permafrost and seasonally frozen ground are very extensive in the high latitudes of earth. Also, resource development and population in these areas are increasing. Because of climatic change, the permafrost is not in thermal equilibrium. Instead, it is warming in many areas, and this needs to be considered in the design criteria for all engineering structures built on permafrost. Warming, with subsequent thawing of permafrost, will affect the surface energy budget, water and gas fluxes (potential for release of greenhouse gases), and vegetation; hence, there is a direct feedback with the climate system. Just as it took a long time for permafrost to develop, it will take a long time for it to completely melt, but the consequences of thawing permafrost can impact our daily lives in the first or second season of melting.

INTRODUCTION

On an extended south-to-north transect at northern latitudes, a transition from ground that never experiences seasonal freezing to those that occasionally freeze during the winter, to those that freeze every year, and to those that may remain frozen for an extended time could be encountered. The topic of discussion in this entry is those surface soils and deeper geologic layers that remain at or below freezing for a duration of 2 years or more and how they impact people living in this environment. Such frozen ground, both unconsolidated and bedrock, is commonly referred to as permafrost.^[1] Although at or below the freezing point of bulk water (0°C), the term “permafrost” implies that neither water is present nor water, if present, is frozen. In fact, it is possible for significant amounts of water to remain unfrozen in permafrost; this is also true for water in seasonal frost.

PERMAFROST CHARACTERISTICS

Spatially extensive permafrost can be found in Russia and Canada as far south as 45° N and even farther south on the elevated Tibetan Plateau and Himalayan Mountains.^[2] Approximately 25 million km² of permafrost exists in the northern hemisphere. In the higher latitudes, permafrost is continuous under the land surfaces. At intermediate latitudes, permafrost is discontinuous or sporadic. Leggett^[3] reported that 20% of the land surface of the world is underlain by permafrost. More than

50% of Russia and Canada is underlain by permafrost. Alaska has continuous permafrost in the northern one-third of the state and discontinuous permafrost in the rest of the state, excluding the coastal areas from the Aleutian Islands to southeastern Alaska (Fig. 1). In the southern hemisphere, permafrost distribution is confined to Antarctica and high alpine or mountainous regions. Isolated permafrost is common at higher elevations, and evidence of past permafrost is common in areas that no longer have permafrost. The thickness of permafrost can vary from a thin lens of less than 1 m to greater than 1000 m (Fig. 1). Permafrost can also be found in coastal areas at the bottom of seas.

Permafrost ground is interesting to the engineer and scientist because the medium is usually composed of two solids (porous medium and ice) and two fluids (air and liquid water). The more components that are present in a mixture, the more difficult it is to predict the medium's response to an input of energy or mass. The amount of unfrozen water in saturated ground is strictly a function of the grain size (more specifically, surface area) and the freezing temperature. A fine-grained soil such as clay has a very high surface area relative to coarse-grained soils such as sand; in frozen ground, this translates into much higher unfrozen water contents at the same temperature. The unfrozen water found in permafrost exists as a film of water around each soil particle. It is via these unfrozen films that water moves in permafrost. Frozen clay can have as much as 5–7% unfrozen water by volume at –15°C. As the temperature decreases, the amount of unfrozen water also decreases. Thermal and hydraulic properties of permafrost are quite

Fig. 1 The schematic representation of permafrost distribution in Alaska on a south-to-north transect.

variable and depend on the percentages of the various ground components. Most heat transfer in permafrost is by conduction and can be modeled by Fourier's law although simpler methods have been developed.

A typical temperature profile of permafrost is shown in Fig. 2. Since there is a geothermal flux outward from the center of the earth, this heat has to be successfully transferred to the ground surface or the permafrost will warm and melt. In order to maintain the thermal integrity of the permafrost, the soils above the top of the permafrost table must completely freeze during the winter, and so there is a continuously decreasing thermal gradient along which the geothermal heat can be transferred to the surface by conduction (Fig. 2).

The seasonally thawed soil layer at the ground surface that goes through freezing/thawing annually and mantles the permafrost is called the active layer (Fig. 2). This layer acts as a buffer to heat and mass transfer to the permafrost. A typical active layer in the continuous permafrost zone would typically thaw to a maximum depth of 60 cm. The top layers within 15–25 cm of these soils are generally

Fig. 2 Typical temperature profile for permafrost, with annual variation indicated near the ground surface.

composed of organic material, with the deeper soils being mineral. Organic soils are good thermal insulators, and when coupled with snow cover during the winter months, they minimize heat loss from the ground. The thermal balance of the permanently frozen ground is maintained by heat loss to the atmosphere that occurs at high latitudes over the extended winter months.

Permafrost is usually considered to be impermeable to water movement. This is usually a good assumption for short durations of days or even a few months. For longer periods of time, the redistribution of water within permafrost can be appreciable. During snowmelt and major rainfall events, considerable water enters the active layer. Most of this water resides in the organic soils as the mineral soils are usually already near saturation. Since permafrost has relatively low hydraulic conductivity, there is no hydraulic connection between the perched water above the permafrost (suprapermfrost groundwater) and the subpermafrost groundwater below the permafrost (Fig. 2). In continuous permafrost, the subsurface hydrology is confined to the active layer. For areas of discontinuous permafrost, the subsurface hydrology is a combination of shallow flow over the frozen ground and deeper flow around and under it.

SURFACE ENERGY BALANCE

Any time the ground surface is disturbed, the surface energy balance that sustains permafrost is upset. This generally results in warming of the permafrost and thickening of the active layer. Much sporadic and discontinuous permafrost is maintained at temperatures just below freezing; climatic warming of just a few degrees would result in the melting of this frozen ground and warming of colder permafrost. Also where permafrost exists, surface disturbances such as removing vegetation or surface soils and ponding of water are sufficient to alter the surface energy balance and cause permafrost degradation. Permafrost generally appears where the mean annual surface temperature is at least a few degree Celsius below freezing; for instance, Hay River, Northwest Territories, Canada, has sporadic, shallow permafrost with a mean annual temperature of -3.4°C .

In areas of discontinuous permafrost, the south-facing slopes are generally permafrost free (Fig. 1), while north-facing slopes have permafrost; the east- and west-facing slopes and valley bottoms may or may not have permafrost, depending on subtle site-specific conditions that impact the energy balance (vegetation, slope, moisture content, etc.). Because it took thousands of years for permafrost to develop, deep permafrost is particularly a good recorder of past climates, and changes in the temperature profile will reflect these impacts. Many general atmospheric circulation models predict variable global warming in the high latitudes, and in some areas, there is

already field evidence of atmospheric warming^[4] and permafrost warming.^[5] To sustain permafrost, the geothermal heat radiating out from the core of the earth must be removed; this only occurs if the active layer is completely frozen during winter.

LIVING WITH PERMAFROST

Permafrost influences many facets of everyday living that are often taken for granted in warmer climates. Permafrost negatively impacts both the quality and the quantity of the available groundwater and limits the potential for the infiltration of wastewater. As a result, housing units with individual water and wastewater systems must be designed with innovative options to replace the traditional groundwater well and septic system for wastewater treatment. Utilities that are typically buried are often placed in aboveground utilidors. Also as roadways age, they become very bumpy as differential movement of the road surface occurs.

The significant property of permafrost from an engineering viewpoint is the ice content. The amount of ice can range from essentially none in well-drained ground to values that exceed the porosity of poorly drained ground. Within the permafrost, segregated ice with minimal entrained soil exists as ice lenses and wedges. As long as the permafrost stays frozen, the ground is relatively stable. However, thawing of ice-rich permafrost causes ground to settle or subside. This thaw settlement compromises the structural integrity of buildings, roadways, pipelines, and other structures built on it. For areas where construction must take place on frozen ground, special efforts—e.g., the use of insulation and thermosyphons—are necessary to maintain the structural integrity of the permafrost. Thermosyphons are vertical devices for removing heat from the ground, and they are used extensively under buildings and pipelines to maintain below freezing conditions in the ground.

Soil freezing causes additional engineering problems near the ground surface when strong thermal gradients induce water movement from warm ground to cold ground through unfrozen films of water on the surfaces of soil particles, regardless of whether it is frozen or not. This process causes “frost heave,” as it results in an accumulation of ice in the form of lenses that can cause the ground to expand and deform. Surface heaving becomes significant over time periods of several years, and it is important for those engineering structures with design lives of tens of years to compensate for this additional stress.

CONCLUSIONS

Permafrost and seasonally frozen ground are very extensive in the high latitudes of earth. Also, resource

development and population in these areas are increasing. Initial efforts directed at building an infrastructure (roads, airports, water and sewer distribution, etc.) on permafrost assumed that the frozen ground was in thermal equilibrium. It is obvious that because of climatic change, the permafrost is not in thermal equilibrium. Instead, it is warming in many areas, and this needs to be considered in the design criteria for all engineering structures built on permafrost. Warming, with subsequent thawing of permafrost, will affect the surface energy budget, water and gas fluxes (potential for release of greenhouse gases), and vegetation; hence, there is a direct feedback with the climate system. Just as it took a long time for permafrost to develop, it will take a long time for it to completely melt, but the consequences of thawing permafrost can impact our daily lives in the first or second season of melting.

Petrocalcic Horizons

Alain Ruellan

National Superior School of Agronomy of Rennes, Montpellier, France

Abstract

Petrocalcic horizons are strongly developed horizons that have accumulated calcium or other carbonates. Petrocalcic horizons distribution in the soil covers permits to prove the existence of pedological systems, i.e., lateral relationships between morphological features and dynamics of the soil mantle.

INTRODUCTION

In Mediterranean and tropical arid regions, B or C horizons of soils frequently contain, at shallow depths (some decimeters), more than 50% calcium carbonate. Generally, these horizons are layered (platy), hard, and 10–100 cm thick. These Bca and Cca horizons are called “lime crusts,” “calcretes,” or “petrocalcic horizons.” Soils with petrocalcic horizons are extensive on plateaus, slopes, and river terraces.

Petrocalcic horizons are strongly developed horizons that have accumulated calcium or other carbonates.^[1] They are indurated or cemented calcic horizons; vertically, they are related to the A and B horizons above and to C horizon below, which may or may not be calcareous.^[2]

THE CALCIC HORIZONS

Calcic horizons^[3,4] are horizons of calcium carbonate accumulation. In the calcic horizons, the calcium carbonate:

1. may transfer from the top of the soil profile, from the upper part of the pedological toposequence, from the air (wind), and from the underground water.
2. precipitates giving rise to very rich calcium carbonate forms that are either discontinuous (pseudomycelia, cutans, nodules, or veins) or continuous (petrocalcic horizons).

As development proceeds, the carbonate accumulates, first filling the pores and then replacing pre-existing minerals (epigeny).^[5–8]

THE PETROCALCIC HORIZONS

When the calcium carbonate concentration in B or C horizons increases sufficiently to mask all or most of the pedological or lithological structure within which it develops, it becomes a petrocalcic horizon (or calcrete

or lime crust).^[2–4] When consolidated, the carbonate content of the horizon is 50–90%.

There are several types of petrocalcic horizons:

1. Unlayered (non-platy) petrocalcic horizons: the structure can be massive, angular, finely lamellar, or nodular. The color is nearly white.
2. Layered (platy) petrocalcic horizons:

Layered, non-compact, petrocalcic horizons are made up of superposed, clearly individualized layers of crusty material, hard, but not petrified (Fig. 1). The thickness of these layers varies from a few millimeter to several centimeter; they are not continuous vertically but are separated from each other by more or less horizontal fissures arranged in a braided manner. The internal basic structure can be massive, nodular, or finely lamellar; the color is generally white to creamy white, with frequent black spots. As the crusty material becomes harder, it tends to be pink in color.

Layered compact petrocalcic horizons (slabs) (Fig. 2) are made up of one or several calcium carbonate layers, extremely hard, gray- or, more often, pink in color. Each layer can be 10–20 cm thick. These layers are petrified, usually very continuous. The internal basic organization is very massive without fine lamellae.

Finely layered compact petrocalcic horizons are very hard formations with thickness of a few millimeter to a few centimeter. The horizons are clearly stratified, consisting of one or more series of very fine superimposed lamellae; the color being white or pink.

In addition to calcium carbonate accumulation, structures, and hardness, other important data useful for characterizing and distinguishing different types of petrocalcic horizons are water pH and natural drainage:

Fig. 1 Below an A horizon (1) is a layered non-compact petrocalcic horizon (crust) (2), over an unlayered (non-platy) petrocalcic horizon (3), on a calcic horizon (4).

1. Basic types have a water pH between 8.0 and 8.7; ultrabasic types have a water pH > 8.7. A very high pH indicates the presence of magnesium carbonate.^[9]
2. Soils with petrocalcic horizons in environments with restricted drainage tend to form montmorillonite, attapulgite, and sepiolite clay minerals.^[6-8,10]

VERTICAL SUCCESSION OF THE CALCIC AND PETROCALCIC HORIZONS

Below A or B horizons, the accumulation of calcium carbonate can be of three types:

1. Slightly differentiated: the distribution of carbonates is diffuse, sometimes with pseudomycelia with very diffuse upper and lower limits.
2. Moderately differentiated: the carbonates in the calcic horizon occur partly as diffuse distributions in the soil matrix and partly as concentrations, forming cutans, soft and hard nodules, or veins, with diffuse upper and lower limits.
3. Highly differentiated (petrocalcic): the carbonates form laterally continuous concentrations resulting in one or more superposed petrocalcic horizons. The vertical complete succession from the top is: finely layered, over thicker compact layers (slabs), over

Fig. 2 A layered compact petrocalcic horizon (slab) (2) below an A horizon (containing pebbles of slab) (1), over a layered non-compact petrocalcic horizon (crust) (3), on a calcic horizon (4).

thick non-compact layers, over a massive horizon. There are four main types of vertical successions of petrocalcic horizons:

- single massive horizons;
- layered non-compact horizons, over unlayered horizons;
- finely layered horizons, over layered non-compact horizons, over unlayered horizons; and
- finely layered horizons, over layered compact horizons, over layered non-compact horizons, over unlayered horizons.

Petrocalcic horizons always have sharp upper boundaries and carbonate contents that decrease with depth. A gradual transition and discontinuous concentrations of carbonate mark the lower boundary of the petrocalcic horizon. The solum above the petrocalcic horizon is generally between 10 and 50 cm thick.

LATERAL DISTRIBUTION OF THE CALCIC AND PETROCALCIC HORIZONS

As with vertical transitions, progressive lateral transitions frequently occur between different forms of calcic and petrocalcic horizons. From this, it can be concluded that the vertical and horizontal structures of calcium carbonate accumulation result from the same mechanisms.

In a landscape, the lateral distribution of the calcic and petrocalcic horizons is mainly a function of topography and age.

Along a slope or pediment, calcic horizon development increases downslope. In a complete toposequence (catena), differentiation progresses from a soil with minimal calcic horizon development upslope, to a soil with moderate calcic horizon development immediately downslope, and finally to soils with more and more strongly developed petrocalcic horizons, the different types and superposition of petrocalcic horizons appearing successively (Fig. 3).

In time, calcic horizons evolve (Fig. 3) from diffuse carbonate distributions to discontinuous accumulations (pseudomycelia, cutans, nodules, or veins) to unlayered petrocalcic horizons to layered non-compact petrocalcic horizons to slab. The finely layered (ribboned) horizons can exist as soon as non-compact layered horizons appear.

On the other hand, decarbonation of the A and B horizons above the calcic and petrocalcic horizons does not increase with age. It is only on the younger Quaternary surfaces that a small decarbonation can be observed as these surfaces age. However, this decarbonation does not increase on the older surfaces and, when petrocalcic horizons appear, the calcium carbonate content of the upper horizons may increase due to erosion and subsequent formation of the upper horizons from the calcrete.

These facts confirm the following interpretations:

1. There is a logical order of appearance of the calcic and petrocalcic accumulations and horizons; this logical order is the same in space, vertically and laterally, and in time. These accumulations and horizons are thus genetically linked, by toposequences and chronosequences.

Fig. 3 Relationships between calcic and petrocalcic horizons in space and time (North Morocco). The length of the sequences may vary between some tens and several hundreds of meters; the difference in altitude, between the old and recent Quaternary surfaces, is some tens of meters.

Source: From Soil Survey Staff.^[1]

2. The vertical leaching of the calcium carbonate, which impoverishes the upper horizons in favor of the calcic and petrocalcic horizons, is a limited phenomenon; the major part of the calcium carbonate that accumulates in the soils comes from lateral redistributions.

In arid and semiarid regions, which are the privileged domains of the petrocalcic horizons, calcic and petrocalcic horizons can occur in soils formed from non-calcareous or non-calcic rocks: this happens when landscapes upstream furnish calcium by lateral lixiviation. However, in very arid regions near the sea, very strong petrocalcic horizons occur in soils formed from non-calcareous, non-calcic rocks without possible upstream sources of calcium. So calcium carbonate can also arrive by air as calcareous dust and calcium from sea spray.

SOIL USE

Petrocalcic horizons in soils at depths <50 cm limit the soil's agriculture uses, because of the physical (hardness and low porosity) and chemical (calcium carbonate, high pH) obstacles the horizon constitutes for the roots. It is possible to fracture the non-layered and the layered non-compact petrocalcic horizons to facilitate the penetration of water and roots for cotton, alfalfa, or fruit trees, but it is impossible to fracture when slabs are present, and it is costly too. Chemically, the non-layered, hard but non-compact petrocalcic horizons are more crop limiting because they contain too much active calcium and magnesium carbonate. Layered petrocalcic horizons in some areas are used for the construction of houses and building of roads.

CONCLUSION

Petrocalcic horizons distribution in the soil covers permits to prove the existence of pedological systems that is lateral relationships between morphological features and dynamics of the soil mantle.

pH

Grant W. Thomas

University of Kentucky, Lexington, Kentucky, U.S.A.

Abstract

pH and buffering (reserves) of soils are controlled by a number of soil components such as clay minerals, organic matter, oxides of aluminum and iron, and compounds of calcium and sodium. In a few cases, the oxidation of sulfide overrides these more common controllers of pH, causing exceedingly low pH values. Including the latter, a range of pH values from 2 to 10 can be encountered. In most soils, however, a pH range of 4 to 9 is more common. The chemical reactions that control the soil pH are usually what interest us. In other words, pH reveals the reactions that dominate the soils. As such, pH is very useful as a clue about what must be done to the soil to make it ideal for the purpose we desire. No other single soil measurement gives us so much information so easily.

WHAT SOIL pH VALUES MEAN

Although pH values are not adequate to determine lime requirement, they do indicate rather precisely what is going on in the soil in terms of the major chemical reactions. In addition, pH infers secondary reactions such as the availability of both primary nutrients and micronutrients. The major pH categories are described below, together with their significance.

THE PRESENCE OF FREE ACIDS

Soil pH values around 2 to 3 indicate the presence of a free mineral acid. In almost all cases, the acid is sulfuric acid (H_2SO_4) which generally arises from the oxidation of iron (Fe) sulfides. The usual reason for their oxidation is exposure to the atmosphere during surface mining, excavation during construction, or drainage of submerged soils. Obviously, not all materials contain sulfides, but if they are present, exposure begins their oxidation, and the oxidation results in free H_2SO_4 . This acid then begins to dissolve soil components, including the clay minerals. If pH in the range of 2 to 3 persists with time, this indicates that there is sufficient free acid present to dominate all soil reactions. The long-term effect is the virtual dissolution of clay minerals.

In addition to the long-term destruction of the soil, plant growth is almost totally inhibited and the cost of neutralizing the acidity will be very high. On a practical level, neutralization of free acid is too expensive to attain by depending of the income received from growing crops. Therefore, it usually is achieved only by high expenditures for agricultural limestone, commonly mandated by government regulation; e.g., the use of 100 Mg of calcium carbonate (CaCO_3) per hectare is

commonly required to neutralize the free acid. That amount of limestone commonly costs more than the value of the land treated.^[1]

THE PRESENCE OF Al^{3+} IONS

At pH values of 4 to 5, trivalent exchangeable aluminum (Al) is always present in soils unless they are quite high in organic matter. The pH of the soil is dominated by the hydrolysis reaction:

which has a minimum pH of 3.84 in montmorillonite and a maximum pH of 4.89 in hectorite.^[2]

This pH range indicates problems with the growth of most crop plants because root growth is strongly inhibited by the presence of Al^{3+} . Nevertheless, the case is not nearly as serious as with free mineral acid for two reasons: First, plants are not killed outright, and second, correction of the problem usually is not an economic impossibility. Instead of requiring 100 Mg of CaCO_3 per hectare, a range of 5 to 10 Mg per hectare is generally sufficient to correct the problem, and this treatment will last for several years and will produce crop yield responses that will pay for the treatment.

THE PRESENCE OF HYDROXY-AL

At pH 5.5 and above, there is no longer any significant trivalent, exchangeable Al.^[3] The chemistry is dominated by complex, polymerized hydroxy-Al of the general composition:

These polymers are not exchangeable from either clay minerals or organic matter^[4] so that they are reactive only with the H⁺ ions formed by nitrogen fertilizer (or acid rain) or OH⁻ ions that come from the application of lime. The adsorption of H⁺ tends to reduce the OH⁻ ratio, and the OH⁻ tends to raise it—to a maximum of three, where the charge becomes zero.

Because of these characteristics, hydroxy-Al and, in some soils, hydroxy-Fe form the so-called pH-dependent charge in soils. In the case of clay minerals, the hydroxy-Al polymers lose positive charge by gaining hydroxyls. In the case of organic matter, the hydroxy-Al polymers block the strongest carboxylic groups effectively reducing the ionization of the remaining carboxylic groups at a given pH.^[5,6] Thus, in both mineral and organic fractions, the effect of the hydroxy-Al polymers is to make the soil an apparently weaker acid that greatly increases the buffer capacity.

Although hydroxy-Al is not directly toxic to plants as trivalent-Al is, it does have a negative effect of short-term phosphorus (P) availability because it represents a sink for soluble P. Whether this has a practical effect on long-term P availability is not at all clear because Al phosphate is surely one of the dependable sources of P in acid soils.^[7]

NEUTRAL SOIL: pH 6 TO 7

A soil with pH 6 to 7 is free of trivalent exchangeable Al, has variable levels of non-exchangeable hydroxy-Al, and has calcium (Ca) as the dominant exchangeable cation. In addition, there are no elements such as manganese present in toxic quantities. On the other hand, manganese, zinc, boron, and Fe are usually available in amounts adequate for good crop growth. The pH range of 6 to 7 increases molybdenum availability, which, in turn, favors crops that depend on nitrogen fixation, such as soybeans and alfalfa. This pH also favors mineralization of organic nitrogen with the eventual formation of nitrate nitrogen.

Hence, the pH range of 6 to 7 generally indicates optimum soil conditions for crop growth, with the fewest negative consequences.

THE PRESENCE OF CaCO₃

Passing to alkaline soils, the presence of excess CaCO₃ in the soil is diagnostic in the pH range of 7.6 to 8.3, depending on the partial pressure of carbon dioxide (CO₂). In this pH range, a fizz test with hydrogen chloride will reveal the presence of CaCO₃, which shows there is no need to worry about the use of lime because soil acidity will not develop. In addition, soil structure usually is superior because Ca so dominates the system. On the other hand, the availability of certain elements

such as zinc, manganese, and Fe can be reduced enough to cause deficiency problems. On the whole, a calcareous soil is favorable, but some problems can arise. Knowing whether a soil is calcareous or not can be very important in a landscape that has both calcareous and non-calcareous soils, a common occurrence. Treatments for soils and crop variety response will vary with the presence or absence of CaCO₃ in the soil.

THE PRESENCE OF SODIUM CARBONATE (Na₂CO₃)

As pH values rise above pH 8.3, the cause is invariably the presence of Na₂CO₃. As the problem worsens, the pH can rise to 9 and even 10. In this pH range, most exchangeable Ca is precipitated as CaCO₃, leaving the soils dominated by exchangeable sodium. Soil structure gradually deteriorates because both clay minerals and organic matter are dispersed. As a rule, water infiltration is greatly reduced as is internal drainage in the soil. The result is that dry soils stay dry and wet soils stay wet so that crop growth is strongly inhibited and soil productivity declines radically. Rooting is poor, and as an additional restrictive factor, Fe deficiency is common.

Because this transformation to sodium-dominated soils does not occur uniformly, the usual situation is a normal landscape interspersed with sodium-affected circles. Crop growth is so much inferior within these circular zones as compared to growth in the normal soil areas that it is quite easy to determine the proportion of the land that is strongly affected by sodium. It is very difficult to reverse the soil degradation and make these circular areas productive again. This often results in abandonment of the fields because of poor crop production. Probably, the exception to this is when there are very high value crops such as citrus where treatment with H₂SO₄ and/or gypsum can recover production with time and expense.

A summary of the foregoing discussion on the significance of soil pH is given in Table 1. These values are extremely important in field diagnosis; a table such as this carried in the clipboard or in the head is of constant value in making recommendations.

Table 1 Diagnostic pH values and the dominant reaction at each one.

pH	Dominant reaction
2–3	Free mineral acid, usually H ₂ SO ₄
4–5	Presence of trivalent, exchangeable Al
≥5.5	Presence of hydroxy-Al
≥6.0–6.7	An ideal pH for many crops
7.6–8.3	Presence of CaCO ₃
9–10	Presence of Na ₂ CO ₃

STRENGTH OF SOIL ACIDITY

As was shown clearly in 1931,^[8] there is a wide difference in the strength of soil acidity from one soil to the other. Mehlich^[9] showed similar results and attempted to relate the strength of soil acidity to the clay mineralogy present. Briefly, he showed that montmorillonite was strongly acid, whereas kaolinite was much weaker.

Rich^[10] showed that interlayers of hydroxy-Al greatly reduced apparent acid strength when added to clay minerals. Coleman and Thomas^[11] showed the effect of adding both hydroxy-Fe and hydroxyl-Al to montmorillonite. Whereas pure montmorillonite had strongly acid titration curves, the addition of hydroxyl-Fe or hydroxyl-Al compounds to the clay gave titration curves of very weak acids (Fig. 1).

Both hydroxy Fe and Al compounds act as hydrogen ion sinks, which give exactly the same effect as if the acid were very slightly disassociated. They also act as OH⁻ sinks, which makes the pH very difficult to raise. The positive side of this high buffering capacity is that pH remains quite stable even with the use of high nitrogen fertilizer rates or with a degree of overliming.

ORGANIC MATTER

In the case of organic matter, the differences already mentioned in clay minerals—hydroxyl-Fe or hydroxyl-Al—are

Fig. 1 Buffer curves (in 1 N KCl) for hydroxy-Al and hydroxy-Fe complexes with montmorillonite and for Al-, Fe-, and H-montmorillonites: A. hydroxy-Al complex; B. hydroxy-Fe³⁺ complex; C. Al-clays; D. Fe³⁺-clay; E. H-clay.

Source: From Coleman & Thomas.^[11]

also observed. The strength of carboxylic acids in organic matter should be in the order of pKa~4, where, in fact, most soil organic matter has an apparent pKa of around 6. Martin and Reeve^[5] showed why this was so. Organic matter contained Fe and Al compounds, and as they were removed, the pKa of organic matter approached the expected pKa of 4. Schnitzer and Skinner^[12] demonstrated how common the interaction between hydroxy Fe and Al and organic matter really was.^[6] Fig. 2 shows how strongly the adsorption of Al by organic matter affects apparent acid strength. The exchangeable Al in organic matter is almost insignificant. Instead, Al becomes hydroxylated and virtually non-exchangeable. At pH values of ≥4, the average composition of Al adsorbed is Al(OH)₂⁺.

Fig. 2 The effect of adsorbed Al on Michigan Peat titration curves and on pKa values.

Source: From Hargrove & Thomas.^[6]

Table 2 The effect of organic matter on exchangeable Al in montmorillonite + sand at given pH values.

pH	Exchangeable Al cmol/kg (+)	
	No organic matter	10% organic matter
4.0	1.70	0.25
4.5	1.20	0.05
5.0	0.80	0.02

The fact that organic matter essentially immobilizes exchangeable Al helps explain why it can be so beneficial in acid soils. In two artificial soils made of sand and montmorillonite and with 10% organic matter in one, the amount of exchangeable Al was greatly affected by organic matter, as shown in Table 2.^[6]

OTHER FACTORS THAT AFFECT SOIL pH

Salt Content

The salt content of the soil–water slurry greatly affects soil pH. Salt content tends to be higher in soils that have been fertilized heavily, soils that have been irrigated with fairly high salt water, and samples that have been taken in the fall vs. those taken in the spring.^[13] Increased salt content tends to give lower pH values in temperate zone soils. This pH variation can be from one- or two-tenths, up to perhaps a half unit. In tropical soils, this same salt effect can be exactly the opposite, causing a rise in pH of about the same amount.^[14]

This salt problem has led many researchers to add salts ranging from 0.001 to 1 M to soil–water slurries in an attempt to “standardize” the pH values. The real effect is that the pH values all change, at the highest salt concentration up to 2 units^[15] with the result that there is another set of relationships to record mentally for use in interpretations. In practical terms, adding salt is not generally worth the trouble. It certainly is true that some extreme conditions will give pH values that cause some misinterpretations. But, the vast majority are good enough without adding salt to make reasonable deductions and recommendations.

Dilution

Another factor that can affect pH is the soil/water ratio in the slurry. Diluting soils by 10 times^[16] will raise pH by about 0.4 unit. Since most slurries range from 1:1 to 1:2.5, the change in pH is only about 0.1 unit, which is not a big problem.

Carbon Dioxide

CO₂ content of calcareous soils can affect the pH greatly, pH 8.3 at the atmospheric partial pressure (0.0003 atm) to 6.2 at 1.0 atm. Because soil levels of CO₂ are almost always higher than those in the aboveground atmosphere, there is a tendency for the following reaction to move toward the right.

On dried and ground soil, the effect should be small, but on pH measurements done in the field, this effect can be quite important.

Suspension Effect

In most soils, there will be a reduction in pH when the electrodes are placed in the suspension as compared to the supernatant solution. (In tropical soils, the effect may be exactly the reverse.) This suspension effect has been interpreted in two ways. First, according to Marshall,^[17] the higher activity of H⁺ ions near the clay surface causes the lowest pH. Second, according to Coleman et al.^[18] the suspension effect is mostly from the electrical charge on the soil, which differentially affects the mobilities of K⁺ and Cl[−] in the calomel electrode, not the glass electrode. In a strongly negatively charged soil, the mobility of K⁺ would be high and that of Cl[−] low, while in a positively charged tropical soil the opposite would occur.

It is generally accepted that the suspension effect is largely spurious.^[19] Nevertheless, there is evidence that H⁺ activity is somewhat higher at the clay surface.^[20]

CONCLUSION

Soil pH is one of the most useful, economic, and rapid measurements that can be made on soils. Remembering the reasons for unusually low and high pH values, it also interprets well the intermediate values rather precisely. Because of this, a rapid soil pH value can be one of the most useful measurements taken on the soil, whether the news is favorable or bad.

Abstract

Though we have entered the 21st century, the problems associated with soil phosphorus (P) chemistry still abound. In developing, resource-poor countries, soil P deficiency is as severe a constraint as ever, especially in acid sandy soils and in large areas of Africa, where P fertilizer use is minimal. In such conditions, fertilizer use can potentially have a dramatic effect on crops. However, the main constraint is fertilizer availability on the local market and, when available, being at an affordable price. Factors such as remoteness from ports, inadequate transport networks, poorly developed distribution systems, absence of credit, weak or non-existent extension organizations, poor product prices, and vagaries of weather are some of the main factors militating against fertilizer use in many countries, especially Africa. The inevitable consequence is poor crop yields and poverty and hunger.

INTRODUCTION

Of all the nutrient elements that support life on this earth, phosphorus (P) is the most vital. As one of the three major elements in plant nutrition along with nitrogen (N) and potassium (K), P occurs in the least amount in soils and is the most growth-limiting factor. The growing plant derives this vital nutrient from the soil itself, which is dependent on P concentration in the rocks from which the soil was formed,^[1] or mainly from fertilizers in the case of most commercially grown crops.

Soil P deficiency, on a global basis, has negative implications for crop yields and the entire food chain. Under natural conditions, weathering and dissolution of rocks and relatively insoluble P-containing minerals is a slow process and is only capable of supporting slow-growing vegetation and crops adapted to low soil P availability. The widespread use of fertilizers in the developed world since mid-20th century or so has largely eliminated serious cases of P deficiency in crops, animals, and humans and has been a major factor contributing to increase in food production to feed the world's expanding population.

Few areas of soil chemistry–plant nutrition are as tantalizing as P research. Broad reviews documenting the state of P research, highlighting knowledge gained and challenges ahead, serve as building blocks for what we know.^[1,2] The phenomenon of soluble P reacting with soil constituents, i.e., adsorption/precipitation, results in only a small proportion of applied P (5–20%) being utilized by the first year's crop, and decreasing amounts thereafter, thus

giving rise to the notion of P “fixation.” The review of Larsen^[3] focused on unfertilized soils, considering in detail the equilibria between solution P and various solid phases. A major milestone was “The Role of Phosphorus in Agriculture,”^[1] having authoritative chapters on various aspects of the soil–plant P continuum (Fig. 1).^[4–6]

At the global level, fertilizer use mirrors the country's overall state of economic development. In developed, intensive-agriculture countries, many soils have high P levels due to continuous P fertilizer use. Consequently, there is frequently little or no response to P, and indeed soluble P may be lost from agricultural land, causing eutrophication in lakes and rivers.^[7] Despite this shift in emphasis, the intractable nature of P is an issue in developing and developed countries alike as efforts are made to get the most efficient use of this essential nutrient, with a balance of production and environmental concerns.

This brief overview broadly looks at the equilibria of P fractions or phases in soils; how fertilizer P reacts in the soil from the short- and long-term perspective; the significance of P and its absorption by plants; and how chemical reactions ultimately impact on crop growth and influence the environment—in short, the dynamic nature of P in soils and plants.

SOIL P EQUILIBRIA

Although the total amount of P in soils is 0.1–0.3%, it is chemically variable; the largest fraction is inorganic,

Fig. 1 Crop response to P fertilizer in the field.

with a smaller organic fraction, the relative distribution between the two fractions being dependent on the particular environment and soil type.^[3] In acid soils, various amorphous and crystalline forms of iron (Fe) and aluminum (Al) oxides dominate, while in calcareous soils P is found mainly in the form of calcium (Ca) compounds of varying solubility. However, as there is little or no relationship between total P and the relatively tiny fraction that is plant available (less than 1%), the main focus as far as crop production is concerned is the equilibria or dynamic changes in P solubility that influence crop nutrition.

The immediate source of P for growing plants is the soil solution, which is very low in P, i.e., a few mg kg^{-1} or even less, i.e., intensity factor. Labile P refers to a more sizeable fraction (capacity) and the rate that is capable of replenishing the tiny pool of solution P during plant uptake, i.e., buffering capacity. Within any one crop season, this exchange takes place many times as P is removed from the solution phase, and a new equilibrium is continually

re-established, albeit at a lower level. When root absorption is rapid during active growth, solution P levels may drop to such an extent as to limit growth. Similarly, slow release rates from the labile phase may limit growth. The labile phase represents a suite of soil P compounds of varying degrees of solubility. The non-labile P is that fraction of total P, often the largest, that is inert and has no short-term influence on labile or solution P.

The equilibria among the three P phases of varying solubility under natural conditions are disturbed mainly by plant P uptake.^[3] Fertilization raises solution P levels initially, but this is subsequently followed by a slow, inexorable shift in the direction of less-soluble P compounds. Thus, Johnston^[4] illustrated an agronomically embracing P cycle, including an expanded concept of “P pools” representing a continuum of availability, crop P uptake and removal, and the potential for P loss through leaching and erosion (Fig. 2). This raises the issue of the reactions that occur when soluble P fertilizers are applied to soils.

Fig. 2 Schematic representation of the soil-P cycle under fertilized conditions.

SOIL-FERTILIZER P REACTIONS

The reactions of soluble P fertilizer with soil constituents causing reduced P solubility and availability can be categorized as short-term and long-term ones;^[8] a reversal of this process, desorption, can also occur.

Initial Rapid Reactions

Early research on removal of soluble P from soil solution identified two mechanisms: precipitation, based on solubility products of soil-P minerals, readily occurs with cations such as Ca, Al, and Fe in the soil solution and adsorption occurs on solid-phase surfaces. The understanding envisages more refined mechanisms for P retention, including physical adsorption, chemisorption, anion exchange, surface precipitation, and precipitation of solid phases. Soil P reactions are usually a matter of minutes to several hours depending on soil constituents.^[9] Sorbed P can vary by several orders of magnitude depending on soil type. These reactions can be described by short-duration soil: soluble P equilibration studies using adsorption isotherms, e.g., Langmuir, Freundlich, etc. In practice, it is difficult to partition the different soil P reactions; the process is a continuous one—rapid at first, but continuing slowly to a more stable hypothetical equilibrium state whereby metastable compounds revert to more stable ones. In short, more and more of the plant-available P gets converted to less available or insoluble forms, if not taken up by the plant.

Slow Reaction Phase

Although initial reactions may indicate the magnitude of long-term P availability, they may not always dictate the ultimate direction. Studies of longer duration range from incubation experiments of several months^[10] to studies of a few years or more.^[11,12] Barrow^[13] gave an overview of the transformation process of initial metastable P to less available forms. The changes that occur within months to years can be monitored by crop growth or uptake responses or by changes in availability indices or by relative changes in soil chemical fractions;^[12] when considered together, these approaches clearly reflect the slow transition to insoluble or inert P compounds. The actual mechanisms whereby P reacts under prolonged P:soil contact are unclear; some arguments include migration of adsorbed P from original sites, occlusion of adsorbed P, and slow crystal formation of precipitated P compounds. The reversion process is influenced by soil moisture and aeration, fertilizer mixing or incorporation in the soil, fertilizer form (granular or powder) as well as mycorrhizae, and other modifying influences of the growing plant.

Under field conditions, the general reversion or transformation of P to less soluble forms can be influenced by leaching, especially in coarse-textured soils,^[7] and assimilation of soluble/available P in the soil microbial biomass.

Conversely, mineralization of organic P sources can contribute to the available P pool. Tillage or the extent of soil disturbance can also influence residual P. Given the many and varied influences on the fate of residual P, loss of P-fertilizing effectiveness tends to decrease with time. Barrow^[13] suggested that geometric progression may describe the rate of change of effectiveness over a period of a few years but may not do so within a larger timescale.

Desorption

Any discussion on P dynamism in soils has to consider the possible reversal of the normal process, i.e., the extent to which non-labile or sorbed P becomes labile or available P. While sorption quantity–intensity (Q/I) relationships are used to describe P availability in soils, desorption curves reflect P release from soil to plants.^[14] Evidence from exhaustive cropping and successive chemical desorption studies suggest that this process can occur, albeit very slowly. Nevertheless, the relevance of such desorption studies to actual field conditions is tenuous at best given the disparity between the two sets of conditions. The well-documented adsorption–desorption phenomenon observed in normal aerated soils does not pertain to flooded rice soils.

Soil P Availability

Notwithstanding the complexity of soil P reactions and the resulting equilibria, the critical issue for the growing plant is that the soluble P pool is adequately maintained by replenishment from the adsorbed or less readily available pool, i.e., “available” P fraction. In order to assess a soil’s adequacy for crop growth and determine fertilization needs, various chemical indices have been developed to reflect the “available P pool;” these include reagents that range from water to weak acids and bases as well as more methods such as ion exchange resins and Fe-impregnated paper strips that purportedly do not “dissolve” insoluble P fractions. Some of the most common test include Mehlich 1, Bray 1, and Oslen. The emphasis has been placed on multi-nutrient extractants. However, regardless of the method or availability index used, only the growing plant can accurately identify this fraction. Soil P availability in relation to the roots, i.e., “positional availability,” and limited P movement (diffusion) in soils are important considerations for plant growth.

The ideal test or availability index should identify a critical level of soil P beyond which no fertilizer P is needed and should also identify a P-response range. The soils that test very low would require the largest amount of fertilizer P, and decreased P rate as the test level increases to the “satisfactory” level, and no P beyond that point. Whether a fertilizer strategy of buildup or maintenance is feasible depends on economic considerations. A crucial concern for soil P testing in countries where fertilizer P is extensively used or over-used, e.g., United States and Western Europe,

is to identify the threshold value for soil P that is likely to indicate release or loss of soluble P from the soil, with potential to cause contamination of water sources.

P Nutrition of Plants

P, essential for many physiological processes, especially energy functions, is also a major component of numerous plant structural compounds. Some generalizations on soil-plant P relations follow.^[15]

Absorption and Translocation

P is absorbed by plant roots mainly as dihydrogen phosphate ion ($\text{H}_2\text{PO}_4^{2-}$), using metabolic energy. Crop genotypes vary in their ability to absorb soil P and respond to fertilizer P. Plant factors related to these differences include root development (length and geometry), mycorrhizal infection, and the plant's internal P requirement. Thus, differences in P uptake are associated primarily with root characteristics. Conversely, root proliferation is influenced by the P level in various soil profile layers. Growing plants store very little of the P taken up by the roots, so there must be an ample supply in the soil.^[4]

Mycorrhizae increase the efficiency with which crops extract P from soils and thus effectively decrease the external P requirement of many crop species. Legumes are more mycorrhizal than cereals, and hence are relatively tolerant to P deficiency. Notwithstanding the potential benefits of mycorrhizae in relation to crop P nutrition, the intractable problem of introducing mycorrhizal fungi into non-sterile field conditions remains. In short, it is difficult to manipulate these fungal-plant associations, which occur naturally, for practical economic benefit. However, these associations of soil organisms do help to explain differences in P uptake between plant species.

Most P ions entering the root are taken up by the root hairs or outermost cell layers; accumulation in root cell vacuoles competes with the processes leading to accumulation in the xylem and subsequent transport to the plant top. Phosphate passing radially across the root to the endodermis may move in the transpiration stream through the "outer free space" in the epidermal and cortical cell walls and the intercellular moisture films. Phosphate taken into the symplasm moves by diffusion and protoplasmic streaming.

Once absorbed, P is rapidly translocated to all plant parts, upward in the xylem and downward in the phloem. With soil P deficiency, the roots retain a large part of the absorbed P, and needed P for inflorescence development comes mainly from the stem and leaves by retranslocation. With an adequate P supply, the roots retain a smaller proportion of the total, but again most of the P in the stems and leaves is retranslocated to the developing grain heads. In early vegetative growth, the leaves accumulate the major part of the absorbed P, reaching relatively high concentrations. At inflorescence, leaf P accumulation

decreases, and P translocation from the roots may exceed the absorption rate.

Deficiency Symptoms

Plants unable to get adequate P exhibit stunted growth. As P is mobile in the plant, deficiency symptoms first appear on older leaves. In cereals, i.e., wheat and barley, dark green leaves are typical symptoms. In corn, the leaves and lower parts of the stem become purple or reddish. Deficiency affects not only plant growth but eventually decreases the development of seeds and fruits and invariably delays crop maturity.

P Requirement of Plants

Crop species differ in their external (soil solution P concentration), as well as internal, P requirement (plant tissue P concentration) for optimum growth. Lettuce (non-mycorrhizal) requires $0.3 \text{ mg P kg}^{-21}$ in the soil solution, soybean and tomato $0.2 \text{ mg P kg}^{-21}$, corn and sorghum $0.05\text{--}0.06 \text{ mg P kg}^{-21}$, and cassava (highly mycorrhizal) can grow optimally at $0.005 \text{ mg P kg}^{-21}$. Although the magnitude of these differences may seem small, it dramatically affects the amount of P required to attain the soil P concentrations to optimum levels.

P concentration in plant tissues may vary from 0.1% to 1.0%. Critical concentration of nine tropical grasses, nine tropical pasture legumes, and alfalfa fall within the range of 0.16–0.25% P. Values for individual species vary. The generalized critical level for young cereal plants (wheat, barley, and oats) at head emergence is 0.20% P.^[16] P concentration in leaves is greater than whole shoots; critical P concentration for youngest mature rice leaves is 0.33% at mid-tillering and 0.26% at maximum tillering and panicle differentiation. Critical concentration range in ear leaves of corn at tasseling is 0.23–0.25%. Such indices serve as guidelines for assessing P nutrition and serving as a basis for fertilizer P use in crops.

CONCLUSION

As with most chemically complex elements, P exists in a variety of mineralogical species and solubility phases in soils and is an essential part of all plant life. Like N, the dynamic nature of P constitutes a "P cycle", with P being removed in crop offtake and returned to the soil as residues, manures, and chemical fertilizers, primarily derived from phosphate rock. At the chemical level in the soil, the dynamic processes include dissolution, precipitation, adsorption, and desorption, while biological processes are mainly immobilization within the plant roots and bacterial biomass and subsequent mineralization or decomposition.

While there are gaps in our knowledge of soil, fertilizer and plant P at the basic science level—and they may always

persist—much is known from the applied standpoint. We now have a balanced view of the issues at stake for agriculture, resource conservation, and the environment. Indeed, as Johnston^[4] pointed out, “improving the efficiency of P in agriculture and minimizing its loss from soil to water has much to offer not only to farmers, but to society as a whole.” A number of key questions—now largely answered—provide us with the basis of a strategy of integrated plant nutrient management. Knowing the levels of available soil P for different crops and crop-management systems and having at one’s disposal soil and plant tests, which help in such diagnosis, are prerequisites to provide a P balance in nature. Such an approach will ensure high-P use efficiency, both from the soil and fertilizer (organic or inorganic) standpoint, and at the same time avoid damage to our aquatic environment and its attendant health consequences.

Abstract

Since the earliest development of agriculture, animal manures have been applied to cropland to supply essential nutrients and increase crop yield. Modernization of agriculture has been typified by greater yields of both crop and animal products from smaller land areas and a greater emphasis on external inputs such as chemical fertilizers and concentrated animal feeds. Intensification and confinement of animal production have led to a situation in some areas where there are more nutrients available in animal manure than what the local crops require. These excesses of manure have raised concerns about the fate of the nutrients they contain, as losses of nutrients such as nitrogen and phosphorus (P) from agricultural land can cause problems such as eutrophication in rivers and lakes. To address these regional excesses of P, research efforts have been focused on reducing the P concentrations in diets fed to animals, as well as on improving the availability thereof, both of which result in a reduction in the P concentration in manure generated. These dietary alterations affect not only the concentrations of P in manures produced but also the forms of P, their fertilizer value, and environmental impact.

PROGRESS IN NUTRIENT MANAGEMENT PRACTICES

With increasing human population and awareness of environmental problems associated with pollution of rivers and streams with P, the end of the 20th century saw a refocusing of nutrient management strategies from increasing production toward environmental protection, in developed countries.^[1] Initially, nutrient management strategies were aimed at avoiding overapplication of nutrients, and voluntary best management practices were developed. However, manure tended to be applied at a rate to supply crops with sufficient nitrogen (N), which typically leads to overapplication of phosphorous (P), as manures have N:P ratios of around 2:1 to 4:1 (depending on species) while crop requirements have an N:P ratio of 8:1. When P is overapplied to soils, it builds up the soil test P (STP) concentration and over a period of many years, this leads to STP rising to levels in excess of crop requirement.^[2] STP in excess of crop requirement is undesirable, as studies have shown that when STP rises above agronomically optimum values P losses to rivers and streams increase to the detriment of water quality,^[2] and it can also lead to a negative effect on some micro-nutrients, e.g., zinc.

Nutritional Strategies to Reduce the Manure Phosphorus Concentration

In the past, dietary P levels frequently included a safety margin that allows for any potential variation in both the requirement of the animals and the degree of dietary P utilization, with little attention paid to the resultant manure P concentration. However, research in broilers and broiler breeders demonstrates that levels of inorganic P, supplemented to both broiler and broiler breeder diets, may be considerably reduced relative to minimum requirements published by the National Research Council without an adverse effect on performance.^[3,4]

When considering strategies to increase P digestion and retention, species can be split into two categories according to their ability to digest phytate P: ruminants (cattle and sheep) can digest phytate P, while monogastric species (poultry and swine) can digest little. As approximately 66% of the P in corn and soybean is in the form of phytic acid, and these ingredients frequently constitute about 60–90% of the diet, up to 80% of the total fecal P output may originate directly from corn and soybean meal in poultry diets.^[5] The primary strategy to address the low digestibility of phytate P in monogastric species has been the application of exogenous phytase enzymes to these

diets and is done on the basis of replacing 0.1% of available P from supplemental calcium phosphate with a more or less standard amount of enzyme. Alternate strategies other than the use of phytase include the development of low phytate variants of corn and soybean cultivars, because these possess similar, if not greater, potential in reducing manure P excretion. However, the commercial application of these new cultivars has been limited as a result of the practical complications arising from the identity preservation of these ingredients from harvest to point of feeding.

IMPACT OF DIET MODIFICATION ON NUTRIENT MANAGEMENT

The total P and soluble P concentrations in manures have been shown to be affected by dietary P concentration, P contributing ingredients, and dietary phytase supplementation. Total P is important because applications of manure total P contribute to long-term changes in STP. Once optimum STP for crop production is attained, it is beneficial to balance manure total P applications with crop removal of P. This will maintain crop production without raising STP to levels of environmental concern; although in some soils, P can revert to less available forms so P availability needs to be monitored with soil testing. Applications of soluble P in manure have been correlated to soluble P losses in runoff from manure-amended soils, so minimizing the soluble P concentration in manure is important when P losses to rivers and streams are of concern. Reducing the P concentration in animal feeds (high vs. low non-phytate P diets) and using phytase (phytase vs. no phytase diets) can reduce the total and soluble P concentrations in poultry wastes (Fig. 1A and B).^[6] It is estimated that using available technology, dietary amendment can potentially decrease the total P concentration in poultry by 40%, swine by 50%, and dairy by 30%, while advances could raise these figures to 60% for both poultry and swine.^[7] Research on the impact of dietary amendments on soluble P in manure and P losses in runoff from manure-amended soils is at an early stage; however, trends are starting to appear. Supplying P at an adequate level to satisfy animal requirements is generally achieved through a reduction in the added inorganic dietary calcium phosphate component, and results in a reduction in both total and soluble P in the manures generated. While most studies show that feed additives such as phytase reduce manure total P while having little effect on soluble P, this effect is very dependent on the level of dietary P relative to the requirements of the animals.^[6,7] Phytase supplementation to diets containing P in excess of animal requirements, or without an adequate reduction in the P from supplemental calcium phosphate, will result in a potential increase in the water soluble P when expressed on a percentage basis.^[5]

Fig. 1 Effects of diets high and low in dietary non-phytate P, and the impact of dietary phytase on (A) water soluble P in litters and (B) total P in litters produced.

Source: From Maguire, Sims, et al.^[6]

Traditionally, manure application rates to cropland have been decided by individual farmers. However, increasing concerns over the impact of the land application of nutrients in excess of crop requirement on water quality in rivers and streams have led to increasing regulation of land application of manures in many developed countries. These regulations are primarily based on N and P application rates that are often linked to problems identified in localized areas and are based on the levels of soil N and P, and the annual rate of removal of these nutrients through their incorporation into harvested crops. As forage crops typically have an N/P ratio of 8:1 and manure contains N/P ratios of approximately 2:1 to 4:1, nutrient management regulations based on P application may require up to four times more cropland than previous N-based application guidelines. The limitation of available land in areas proximate to intensive livestock production can cause problems associated with what to do with the manure if it cannot be land applied, as other uses of manure are fairly limited and transport costs limit the potential transportation of the wastes over any appreciable distance. If nutrient management regulations are based on P, then reducing the P concentration in manures could greatly alleviate these problems. For example, if one could reduce the total P concentration in a manure by 40%, then application of 40% more manure by weight to meet the same total P application limit would be possible. This may eliminate problems with

excess manure P in some areas of intensive animal production but may not be sufficient for other areas that already have high STP.

CONCLUSION

Dietary amendment to reduce the P concentration in feeds and hence manures generated will help address concerns over the fate of manure nutrients in areas of intensive animal production. If manures have the same N concentrations but reduced P concentrations, then these manures will come closer to meeting crop N needs without oversupply of P. However, dietary amendment alone will not solve the problem of excessive manure P in all areas of animal production. Dietary amendment will, however, certainly help alleviate the situation where applying animal manures to meet crop N requirements leads to overapplication of P, buildup of STP, and eventually increased losses of P to rivers and streams.

Abstract

The economical use of phosphorus (P) is a key issue for sustainable agriculture since natural P resources are limited. In this entry, the influence of microorganisms on the P nutrition of plants is described. Special attention is given to organic matter management and its effects on the microbial turnover of P in soil.

INTRODUCTION

The lack of mineral phosphorus (P) fertilizers in many regions worldwide and the increasing prices lead to an exploration for alternative strategies to improve the P supply of plants. These can be the use of organic matter and raw materials, the cultivation of P-efficient plants, and the application of microorganisms (MOs) able to mobilize P. Organic matter in the soil is one of the most important factors of increasing the productivity in plant production. It can be provided as manure, compost, organic household wastes, green fertilizer crops, or perennial fodder crops. Besides serving as a source of nutrients itself, organic fertilization can improve the availability of nutrients in soil.^[1,2] The mineralization of the organic P compounds in soil is mainly influenced by MOs. On the other hand, the organic matter in soil affects the activity of MOs.^[3,4]

Like plants, MOs are also capable of improving the availability of inorganic P compounds.^[5] This active mobilization of inorganic P sources by plants and MOs is an elemental factor to counteract the loss of P plant availability by fixation and adsorption and thus a source of energy for high P utilization. Plant growth-promoting effects of MOs were found for arable crops as well as for trees (Table 1).^[6]

In the following sections, the influence of MOs on plant P availability is described with special attention on organic matter management.

MICROBIAL P AND ORGANIC MATTER MANAGEMENT

Biological activity and diversity of MOs in soil are affected positively by the supply of organic matter such

as compost^[7] and manure.^[8] The organic matter supply also plays an important role in the successful inoculation of soil with MOs.^[9] Bünemann et al.^[10] emphasized the important role of organic substances in soil for the conversion of P through soil MOs and found that the microbial biomass is limited by carbon (C) and nitrogen (N) rather than P availability. In a laboratory experiment, the microbial P increased substantially when soil was supplied with C and N. The linkage between soil organic C and microbial P is a major reason why cropped soils usually have lower microbial P contents than forest soils or grassland.^[11]

Microbial P uptake and its subsequent release strongly affect the availability of P to plants. P uptake by MOs may be less than, equal to, or greater than P mineralization from organic material. Therefore, P in soil solution can be replenished or depleted during P mineralization, which has consequences for plant P nutrition.^[12]

The microbial turnover of P in soil was defined by Oberson and Joner^[13] as a sum of all microbial mediated transformations and related fluxes of P in soil. It can be described quantitatively by the P flux (ψ) through the soil microbial biomass as follows:

$$\psi = P_{\text{mic}}/T \quad (1)$$

where P_{mic} is microbial P pool and T the turnover time.

Rapid growth of soil microbial biomass resulted in an increase in P_{mic} and a decrease in water-extractable P.^[4] However, immobilization in MOs may retain P in a potentially plant-available form.^[10] The time between P immobilization and re-mineralization depends on substrate quality and soil properties. It was found that the P in bacterial cells, presumably present in organic compounds,

is mineralized within a few days after addition into soil.^[14] Leitfeld, Siebert, and Kögel-Knabner^[7] found compost-derived microbial biomass as an easily degradable C source.

ROLE OF PHOSPHATASES

About 50% of the total P in agricultural soils are present in organic forms, which include a range of inositol, phosphate ester, phospholipids, and nucleic acids among others.^[15,16]

Decomposition by MOs is the dominating process for P mineralization from organic matter and is closely linked to C mineralization. Additionally, P is also released from organic matter through enzymatic hydrolysis outside the cells by phosphatase excretion, a process called biochemical P mineralization. George et al.^[17] found significantly decreased organic P concentrations in the rhizosphere when phosphohydrolase activity increased. The organic NaHCO_3^- and sodium hydroxide-extractable P fractions are supposed to be sources for plant P nutrition since Heilmann et al.^[18] found a significant positive correlation between these parameters and acid phosphatase activity.

Acid or alkaline phosphatases prevail in soils depending on the soil pH.^[19] Acid phosphatases originate from many sources, including plant root exudates and soil MOs. Alkaline phosphatases are produced by soil MOs and soil fauna, whereas higher plants are devoid of alkaline phosphatase. Organisms excrete non-specific phosphatases as well as specific phosphatases such as phytase. Investigations for the excretion of phosphatases were carried out for different MOs, such as *Aspergillus* spp.,^[16] *Penicillium* spp.^[20] (Table 2), and *Pseudomonas* spp.^[21] Unno et al.^[22] found different *Burkholderia* strains to utilize less-soluble phytates [aluminum (Al)-inositol hexaphosphate and iron (Fe)-inositol

Table 2 Activity of acid and alkaline phosphatase in soil ($\mu\text{g p-nitrophenyl g}^{-1} \text{ soil h}^{-1}$) in dependence of the cultivated crop and addition of the fungus *Penicillium bilaii* in a pot experiment (6 kg P-poor sandy loam pot^{-1}) after 7 weeks of vegetation time under greenhouse conditions.

hexaphosphate] in the rhizosphere of lupines. Hayes, Simpson, and Richardson^[23] reported that a range of plants are unable to utilize P supplied as soluble myo-inositol hexakisphosphate. Their growth was improved when either a purified phytase or a phytase-producing MO (*Aspergillus niger*) was added. The growth of maize was not improved when only calcium (Ca) phytate was added to the soil. However, plant growth increased when the phytate in combination with a phytase was added.^[24]

ACTIVE MOBILIZATION OF MINERAL P BY CROP PLANTS AND MOs

Like plants, MOs possess a range of mechanisms to mobilize or desorb poorly available inorganic P. Usually, production of organic acids and excretion of protons improve the P availability in the soil.^[25] Deubel,^[9] Ruppel,^[5] and Bünemann et al.^[10] found *Enterobacter* and *Pseudomonas* strains to dissolve poorly available mineral Fe–P, Al–P, and Ca–P compounds. These organisms secreted organic acids in dependency of the C source given.

MYCORRHIZAL FUNGI

Mycorrhizal fungi, especially arbuscular mycorrhizal fungi (AMF), are considered to be the most important

microbial symbionts for the majority of crops and have a special importance regarding the mobilization and transport of P in soils.^[26] Hyphae of AMF greatly increase the absorbing surface area of the roots, bridge the depletion zone, and grow into areas with an adequate supply of P. The activity of AMF is enhanced by organic matter,^[27] while the increase in the soil P content affects them negatively.^[28] Microbial inoculants, such as rhizobia, *Trichoderma* strains, fluorescent *Pseudomonas*, and *Enterobacter*, added to promote plant growth affect the AMF. Usually, positive synergistic effects were observed.^[29,30]

CONCLUSION AND FUTURE PROSPECTS

In this entry, the potential of different MOs for plant growth promotion and for P uptake was demonstrated. However, practical use in the temperate climate conditions is limited, and a prediction of practical success of applied MO inoculants is difficult. This has different reasons as follows: 1) The successful use of microbial inoculants depends on many environmental factors. Thus, more information is required of microbial P as a function of land use and the environmental factors; 2) caused by the complexity and the strong relation between soil MOs, inoculated MOs, and crop plants, it is very complicated to distinguish between the contribution of each complement to plant P uptake; and 3) the mechanisms for the plant growth promotion by inoculated MOs are not known in detail and are very indifferent. Positive effects on the P uptake of the plants may be based on an increased availability of nutrients in the rhizosphere, positive effects on the root growth and morphology, and the promotion of beneficial plant–microbe symbioses.

Phosphorus: Spatial Speciation in Agricultural Soils

Anja Gassner

*Institute for Crop and Soil Science, Julius Kuhn Institute (JKI),
Braunschweig, Germany*

Abstract

Phosphorus (P) is present in soils not as a definite and easily separated species, but as a continuum of compounds of different compositions and plant availability, in equilibrium with each other. This heterogeneous equilibrium is constantly disturbed by the uptake of the growing plant and by physical, chemical, or biochemical changes in the soil as well as fertilizer input. Within fields and across short distances, these factors can vary significantly in well-defined patterns, resulting in the spatial speciation of P. Consequently, soil P tests, evaluating the P status of a field, have to be adjusted to the site-specific soil characteristics. Furthermore, the interpretation of these results for subsequent management practices has to consider site-specific factors such as topography and past management history. Finally, the concept of spatial speciation should be applied to other nutrients.

INTRODUCTION

Phosphorus (P) mirabilis, the light-bearing nutrient, was probably discovered by an Arabian alchemist named Alchid Bechil, although its discovery is usually attributed somewhat later to Henning Brandt.^[1] Since the early work of Justus Liebig (1803–1873), agricultural researchers have tried to tackle the mystery of P availability to plants. P research intuitively reminds one of Heisenberg's theory: "The more you see, the less you know." Despite the substantial amount of information available about the transformation products of P fertilizer within temperate^[2] as well as tropical soils^[3] and numerous attempts to conduct elaborate soil test methods to predict P availability to crops and algae,^[2] the management of phosphate, a finite nonrenewable resource, is far from being in accordance with the principles of sustainability.^[4]

This is partly because of the prevailing misconception that soil is a homogenous, static entity. P is regarded traditionally as immobile, but its chemical reactivity with environmental factors, acting at different spatial scales and over different time periods, results in the formation of P species, which not only differ in their plant availability but also in their spatial distribution throughout the field. This spatial speciation^[5] is the key for a new approach to assess soil analysis methods.

CHEMICAL SPECIATION OF P

With the exception of small molecular organic P fractions, plants can only utilize P in its soluble form as

orthophosphate.^[6] Unlike carbon and nitrogen, which can be added to the soil system from the atmosphere, the P status of natural systems is essentially controlled by the occurrence of primary apatite minerals.^[7,8] Consequently, the P enrichment of soils depends directly on P inputs by mineral fertilizers and manure. Although the fate of P when applied to soil remains something of an enigma, it is widely accepted that more than 80% is immobilized by the soil because of precipitation and sorption processes,^[3] whereby the limiting step to furnish crop requirements is the dissolution of initial reaction products during the cropping season.^[9]

For a more practical approach, the soil P continuum is thought as three functional pools: a readily available pool, a reversibly available pool, and a sparingly available P pool,^[10] whereby the readily available P pool is related to the so-called "intensity factor," which is a measure of the gradient in the electrochemical potential of the phosphate ions across the adsorbing surfaces of plant roots and, in its simplest form, can be regarded as the P concentration in the soil solution.^[11] This pool represents P that is readily accessed by plant roots. The reversibly available P denotes the soil P reserve that can be converted into soluble (readily available) P, by either living organisms or by weathering during the growth season. This pool relates to the so-called "quantity factor" or "richness factor."^[12] Whereas the sparingly available P is not available on a short time scale such as one or more crop cycles, a small fraction of this pool may become available during long-term soil transformation.

MOBILITY OF P IN SOILS

As a tetrahedral oxyanion, phosphate has a very low solubility in soils and, in general, does not move with solvent fluxes, apart from small distance diffusion.^[6] In this sense, P is regarded as an “immobile” nutrient. Thus the physical movement of P is restricted to the movement of P associated with soil particles and large molecular-weight organic matter (particulated P) by either bioturbation, soil tillage activities, or soil erosion during flow events.^[13,14] This behavior of soil P was recognized long ago by European geographers and since then has been used in archaeology to trace back ancient settlements.^[15] Conway^[16] introduced the use of total P distribution patterns for the analysis of small-scale occupation deposits. For example, one building showed evidence of having been demolished and partially reincorporated into the courtyard of a subsequent structure. The floor area of the remnant original structure was protected by a layer of small stones and contained high levels

of P. That portion of the floor, which was subsequently converted into a courtyard, unprotected by stones, had less total P, having lost it by exposure and erosion. In an agricultural context, this translates to the following conclusions. First, as far as its total amounts are concerned, P applied with fertilizers may not move from the place it is applied to, and, second, keeping in mind that most soils are naturally poor in P, nearly all the spatial distribution of total P in agricultural soils should be more or less random, reflecting only the spatial sum of distribution faults of past anthropogenic activities (e.g., fertilization and animal husbandry). Spatial relationships may only have developed under the influence of erosion processes.^[16]

SPATIAL SPECIATION OF P

During the last years, the study of spatial variation of soil fertility parameters has expanded considerably, but studies

Fig. 1 Spatial distribution of three different P fractions: CaCl_2 extractable P (upper map), Ca-lactate extractable P (middle map), and Aqua Regia extractable P (bottom map), at Kassow (E12°06' and N53°10'), Northern Germany.

that investigated the spatial distribution of soil P generally focused solely on the distribution of so-called plant-available P. The results of these studies showed that plant-available P does not fluctuate randomly but shows distribution patterns with well-defined lag ranges, where the ranges differ, depending on the sampling procedure and scale of investigation (Table 1). For an introduction into geostatistical terminology, see the entry *Geostatistics* (p. 1012).

Additionally, it is generally accepted that the distribution of available P does not necessarily resemble the distribution of total P.^[19] It appears that the speciation of soil P is dependent on site-specific factors and, as such, is a spatial process.^[20–22] In this sense, “spatial speciation” is defined as the chemical reactivity of a nutrient with site-specific

environmental factors, and the subsequent formation of geochemical species that display different spatial dependencies (Fig. 1).^[5]

Insights into the environmental processes that result in the spatial speciation of soil P and, as such, govern the behavior of applied fertilizer are necessary to predict the interconversion and equilibrium distribution of different soil P pools under specific conditions such as geomorphology, field management, and soil types.

The ratio between the readily available P pool (intensity factor) and the reversible available P pool (quantity factor), reflecting the ease of P withdrawal by the plant, is expressed as the “capacity factor.”^[12] The capacity factor, the P adsorption capacity of the soil, is predominantly dependent on the negative surface charges as well as the specific surface area of soil particles, and is mainly a function of the amount and nature of available adsorption sites in the soil.^[23]

For a homogeneous soil, most of the potential adsorption sites will have a similar bonding energy for P. Thus the speciation of P will mainly be a function of the soil pH and the aging of initial reaction products of freshly applied fertilizer P. In this case, the spatial speciation is assumed to be low (Fig. 2). For a heterogeneous soil, the nature of the chemical reactions between P and particle surface is more diverse and the chemical speciation will result in a differentiated distribution of P among soil components. In this case, the spatial speciation is assumed to be more pronounced, as the distribution of different soil components with a particular bonding energy for P will result in a spatial differentiation of P species.

Apart from the site-specific adsorption capacity of a field, site-specific anthropogenic and environmental factors such as management, biological, and physical factors can result in a spatial speciation of P. Whereas the total P—and, therefore, the sparingly available P pool—is relatively inert to short-term environmental impacts, such as fertilizer placement or changes in tillage practices,^[5,24] the reversibly available P pool is most affected by management.^[25,26] Although the readily available P pool is directly influenced by crop selection and management, McDowell and Sharpley^[27] showed that under similar management conditions, the specific adsorption capacity of the soil (capacity factor) controlled the rate of P release into solution.

In a study investigating the spatial speciation of P at three different study sites, which differed in climate, parent material, topography, P fertilizer regime, and land management, the main environmental factors that controlled the spatial distribution of individual P pools were as follows: soil texture for the readily available P; degree of aging of fresh soil P fractions, precipitated from application of soluble fertilizer P, for the reversibly available P; and primary P minerals and geomorphology for the sparingly available P.^[17]

Fig. 2 Variogram maps showing the spatial distribution of the semivariance of different P pools in a loamy sand (right) and a loamy clay (left). The semivariance is a measure of the average degree of dissimilarity between two data points.

CONCLUSION

P is present in soils not as definite and easily separated species, but as a continuum of compounds of different compositions and plant availability, in equilibrium with each other. This heterogeneous equilibrium is constantly disturbed by the uptake of the growing plant and by physical, chemical, or biochemical changes in the soil as well as fertilizer input. Within fields and across short distances, these factors can vary significantly in well-defined patterns, resulting in the spatial speciation of P. Consequently, soil P tests, evaluating the P status of a field, have to be adjusted to the site-specific soil characteristics. Furthermore, the interpretation of these results for subsequent management

practices has to consider site-specific factors such as topography and past management history. Finally, the concept of spatial speciation should be applied to other nutrients.

Phytoremediation

Khan Towhid Osman

Md. Abul Kashem

Department of Soil Science, University of Chittagong, Chittagong, Bangladesh

Abstract

Inorganic soil pollutants include nitrates and phosphates; micronutrients; heavy metals such as copper, iron, manganese, molybdenum, nickel, zinc, arsenic, cadmium, chromium, cobalt, fluorine, mercury, selenium, lead, and vanadium; and radionuclides such as uranium-238, caesium-137, and strontium-90. Major organic pollutants include trichloroethylene, atrazine, trinitrotoluene, gasoline, benzene, toluene, polycyclic aromatic hydrocarbons, methyl tertiary butyl-ether, polychlorinated biphenyls, etc. They are added to soils through industrial processing, solvent and fuel spills, military operations, disposal of industrial, municipal, agricultural and domestic wastes, use of agrochemicals, traffic, etc. These pollutants are hazardous to the health of most life forms including human. Therefore, remediation of soil has become an important environmental consideration. However, the conventional physical and chemical methods, although can effectively remove contaminants, may not be suited for the treatment of widespread yet low levels of contamination of soils. They are expensive and can have high risk of spreading contaminants to non-contaminated areas. Phytoremediation is effective on soils of low level of contamination, has little risk of secondary pollution, and can be applied to most regions and land types as an inexpensive, aesthetically pleasing, and socially acceptable technology for soil remediation. The mechanisms of phytoremediation include phytovolatilization, phytostabilization, phytoextraction, phytodegradation, and rhizofiltration. Many plant species for effective phytoremediation have been identified, and some more have been genetically engineered. For enhancing phytoremediation, some agronomic practices and chemical amendments may be necessary. Details of the mechanisms, factors, and enhancement of remediation are discussed.

INTRODUCTION

Soil pollution has become a serious problem, not alone in the industrially developed countries where huge amounts of organic xenobiotics are synthesized and metal products are manufactured and used, but also in other regions. Organic and inorganic contaminants find their way into the soils through industrial processing; solvent and fuel spills; military operations; disposal of industrial, municipal, agricultural, and domestic wastes; use of agrochemicals; traffic, etc. Major organic pollutants are solvents such as trichloroethylene (TCE); herbicides such as atrazine; explosives such as trinitrotoluene; hydrocarbons such as oil, gasoline, benzene, toluene, and polycyclic aromatic hydrocarbons (PAHs); fuel additives such as methyl tertiary butyl-ether; and the widely discussed polychlorinated biphenyls (PCBs). Inorganic pollutants can occur as natural elements in the earth's crust and are added to soils through anthropogenic pathways. They include plant macronutrients such as nitrates and phosphates; micronutrients such as copper (Cu), iron (Fe), manganese (Mn), molybdenum (Mo), nickel (Ni) and zinc (Zn); non-essential elements such as arsenic (As), cadmium (Cd), chromium (Cr), cobalt (Co), fluorine (F), mercury (Hg), selenium (Se), lead (Pb), and

vanadium (V); and radionuclides such as uranium-238 (^{238}U), caesium-137, and strontium-90. According to NRC,^[1] most frequently priority pollutants at hazardous waste sites in North America and Europe are TCE, Pb, benzene, toluene, Cr, dichloromethane, Zn, 1,1,1-TCE, As, chloroform, dichloroethene, vinyl chloride, barium, ethyl benzene, Ni, di(ethylhexyl)phthalate, xylenes, and phenol. Persistent organic pollutants (POPs) and heavy metals are particularly hazardous to the health of most life forms, including microorganisms, plants, animals, and humans. Many of these contaminants reach concentrations in soil to toxic and lethal extents, and many of them are carcinogenic to human. Moreover, soil pollutants may contaminate other environmental components. Concern has also arisen because these persistent and toxic xenobiotics are biomagnified along trophic webs and transported over long distances. So, remediation or the improvement of contaminated sites through prevention, minimization, or mitigation of damage to various life forms has become a dire necessity for the existence of ecosystems. Several *in situ* or *ex situ* physical, chemical, and biological cleanup methods involving: 1) removal of harmful chemicals from the environment; 2) treatment of harmful chemicals to change into less harmful forms; and 3) containment of

harmful chemicals left in the ground to prevent them from spreading within the environment have evolved. The conventional physical, chemical, and engineering methods can remove contaminants or reduce their hazards often rapidly and effectively from highly polluted sites in confined areas but may not be suited for the treatment of widespread yet low levels of contamination found in soils of many parts of the world. Moreover, there is high risk of spreading contaminants to non-contaminated places and most of these methods are prohibitively expensive.^[2] Meanwhile, phytoremediation, which is used by plants to extract, sequester, and/or detoxify pollutants, has emerged with a set of low technology and low cost but effective and viable techniques that can be carried out on soils of low level of contamination over small or larger areas with little risk of secondary pollution.^[3] Phytoremediation consists of a set of innovative technologies based on the unique extractive and metabolic capabilities of plants to clean up heavy metals, pesticides and xenobiotics, organic compounds, toxic aromatic pollutants, acid mine drainage, etc. Phytoremediation should be applicable to most regions, climates, and land types as an effective, non-intrusive, inexpensive, aesthetically pleasing, and socially acceptable technology for remediation of soil and water. Phytoremediation is cheaper than conventional remediation methods, which does not require expensive equipment or highly specialized personnel, can be applied *in situ*, and does not disturb soil and spread contaminants.

MECHANISMS OF PHYTOREMEDIATION

The following five general mechanisms of phytoremediation are generally recognized: phytovolatilization, phytostabilization, phytoextraction, phytodegradation, and rhizofiltration.^[4] Table 1 gives examples of some contaminants

in soil and water that can be removed through these mechanisms.

Phytovolatilization

Phytovolatilization is the removal of contaminants from water and soils by plants through absorption by roots and the subsequent release of an unchanged volatile contaminant, a volatile degradation product of a contaminant, or a volatile form of an initially non-volatile contaminant from the stomata at the leaves, where gas exchange occurs.^[10] This strategy of remediation differs from others, which has no control over the migration of contaminants to other areas after releasing them into the air. The contaminants may be degraded by hydroxyl radicals or stay in the air as a pollutant depending on the chemical properties of the contaminant. Some plants absorb the metals Hg and Se by the roots from polluted soils and volatilize them by the foliage into the air. Sites for phytovolatilization may not require much management after the original planting and it involves minimal site disturbance, less erosion, and no need to dispose of contaminated plant materials. However, phytovolatilization efforts should be carried out at sites away from population centers because release of toxic substances may affect human health. It may not be successful at places with unique meteorological conditions that promote the rapid redeposition of volatile compounds. On the other hand, some studies on volatilization of Se and Hg revealed that the pollutants were dispersed and diluted to such an extent that volatilization did not pose a threat.^[11] Volatilization of Se involves assimilation of inorganic Se into the organic selenoamino acids selenocysteine and selenomethionine (SeMet). SeMet is methylated to form a volatile, less toxic compound, dimethylselenide (DMSe). Se enzymes of the S assimilation pathway mediate Se volatilization. Overexpression of one of these enzymes, cystathionine-γ-synthase, promotes Se volatilization. Volatile Se compounds, such as DMSe, are less toxic than inorganic forms of Se found in the soil.^[12] Se contamination is a serious problem in many parts of the world where there are areas of Se-rich soil. Indian mustard and canola (*Brassica napus*) may be effective for phytovolatilization of Se. Some natural plants, which can volatilize Hg very slowly from soil, cannot be considered effective in Hg remediation processes. It inspired to engineer plants with a microbial gene, *merA*, which encodes an enzyme that catalyzes the reduction of tissue Hg(II) to volatile and less toxic Hg(0).^[13] Phytovolatilization of organic contaminants, such as TCE, can also occur in conjunction with other phytoremediation processes. In a study of poplar cuttings in hydroponic solution, about 20% of the benzene and TCE in the initial solution was volatilized from the leaves, with little remaining within the plant. Once released into the atmosphere, compounds with double bonds such as TCE and perchloroethylene could be rapidly oxidized in the atmosphere by hydroxyl radicals. About 10% of toluene, ethylbenzene, and xylene

Table 1 Some contaminants in soil and water and mechanisms of their phytoremediation.

Phytoremediation mechanism	Contaminants
Phytovolatilization	Chlorinated solvents, Hg, and Se ^[5]
Phytostabilization	Heavy metals, phenols, and chlorinated solvents ^[6]
Phytoextraction	Cd, Cr, Pb, Ni, Zn, radionuclides, BTEX, pentachlorophenol, and short chained aromatic compounds ^[7]
Phytodegradation	Nitrobenzene, nitroethane, nitrotoluene, atrazine, and chlorinated solvents like dichlorodiphenyltrichloroethane, chloroform, PAH, BTEX, PCB, and tetrachloroethane ^[8]
Rhizofiltration	Heavy metals, radionuclides, and organics ^[9]

was volatilized. There was little volatilization of nitrobenzene and no volatilization of 1,2,4-trichlorobenzene, aniline, phenol, pentachlorophenol, or atrazine.^[14] Phytovolatilization is most applicable to contaminants with a Henry's constant $K_H > 10 \text{ atm m}^3 \text{ water} \cdot \text{m}^{-3} \text{ air}$, such as benzene, toluene, ethylbenzene, and xylenes (BTEX), TCE, vinyl chloride, and carbon tetrachloride.^[15] Chemicals with $K_H < 10 \text{ atm m}^3 \text{ water} \cdot \text{m}^{-3} \text{ air}$ such as phenol and pentachlorophenol are not suitable for the air-stripping mechanism because of their relatively low volatility.^[16]

Phytostabilization

Phytostabilization refers to the reduction in the mobility and bioavailability of environmental pollutants through absorption into and adsorption onto roots, or precipitation within the root zone of plants, and prevention of contaminant migration via wind and water erosion, leaching, and soil dispersion. The principal advantage of phytostabilization is that the disposal of hazardous residues is not required and it is very effective when rapid immobilization is needed to preserve groundwater and surface water.^[17]

Metals are chemically precipitated or sequestered by complexation and sorption within soils, sediments, and mine tailings. Plants stabilize metals in different ways:^[18]

1) Plants harvest water in the root zone and transpire several hundred thousand liters of water per hectare during the growing season. Removal of water from soil has a significant impact on the volume of water that would move downward to reach the groundwater table. It reduces contamination of groundwater with metals and As; 2) Plants stabilize the landscape from erosion, greatly reducing surface water runoff and sediment available to receiving streams. Plants also reduce erosion caused by wind; 3) Plants absorb metals and As and sequester them in their tissues for a considerable period of time. Surface phenomenon of root exudates is also an important potential mechanism of phytostabilization. For example, binding of Cu to root exudates of two cultivated plants, wheat (*Triticum aestivum*) and rape (*B. napus*), and two weeds associated with wheat, dog daisy (*Matricaria inodora*) and cornflower (*Centaurea cyanus*), was reported by Sylvie et al.^[19] Phytochemical complexation in the root zone, transport protein inhibition, and vacuolar storage in the root cells are the three mechanisms of phytostabilization.^[20] Grasses, sedges, forage plants, and reeds with high transpiration rates are widely used in phytostabilization. The combinations of hardy, perennial, dense rooted plants or deep rooting trees (e.g., poplar and cottonwoods) have a particularly positive effect on the remediation of soil contamination.

Phytoextraction

Some plants can absorb considerable amounts of contaminants from polluted sites and store them in their biomass that can be harvested, treated, and disposed. The process of

using this capacity of plants for successful remediation of pollutants from the environment is called phytoextraction.^[21] Some metals can be locked for a long time in the wood of trees, and then the mechanism is called phytosequestration. Phytoextraction, known also as phytoaccumulation, can isolate and remove contaminants from soil without destroying its structure and fertility. It is suitable for the remediation of diffusely polluted areas, where pollutants occur only superficially at relatively low concentration. Factors such as availability of suitable native plant species, growth rate, element selectivity, resistance to diseases, method of harvesting, and disposal are important aspects regarding success of phytoextraction.^[22] A number of plant species of different families have the unique ability to grow on metal contaminated or metalliferous soils and to accumulate extraordinarily high amounts of heavy metals in the aerial organs, far in excess of normal levels, without suffering from phytotoxic effects.^[23,24] For example, species of the genus *Alyssum* may accumulate tissue concentrations exceeding 2% of plant dry weight of Ni and species of the genus *Thlaspi* may accumulate more than 3% Cd and 0.8% Pb.^[25] Although Jaffre et al.^[26] reported for the first time high accumulation of Ni in the New Caledonian tree species *Sebertia acuminata*, the credit of coining the term hyperaccumulator goes to Brooks et al.^[27] for plants that actively take up exceedingly large amounts of one or more heavy metals from the soil, translocate to the shoot where they accumulate in aboveground organs, especially leaves, at concentrations 100–1000 fold higher than those found in non-hyperaccumulating species. The term hyperaccumulator referred initially to plants that could accumulate more than 1000 mg kg^{-1} Ni (dry weight) in the shoot which was an exceptionally high heavy metal concentration because in most plants Ni toxicity starts from 10 to 15 mg kg^{-1} in vegetative organs.

Threshold values were successively provided for hyperaccumulation of other heavy metals. Hyperaccumulators are plants that, when growing on native soils, concentrate $>10,000 \text{ mg kg}^{-1}$ (1%) Mn or Zn; $>1,000 \text{ mg kg}^{-1}$ (0.1%) As, Co, Cr, Cu, Ni, Pb, Sb, Se, or Ti; and $>100 \text{ mg kg}^{-1}$ (0.01%) Cd in the aerial organs, without suffering from phytotoxic damage.^[28] So far, about 450 angiosperm species have been identified as heavy metal (As, Cd, Co, Cu, Mn, Ni, Pb, Sb, Se, Ti, and Zn) hyperaccumulators. However, new reports of this kind of plants continue to accrue adding new plants to the list of hyperaccumulators.^[29] However, most of these plants are of low biomass, slow growing, or are adapted to extreme environments and can accumulate only one or few specific metals.^[30] Besides a high concentration of metals in aboveground parts, hyperaccumulator plants meet the following requirements: 1) the metal concentrations in shoots must be greater than that in roots; 2) aboveground metal concentrations must be 100–500 times higher than those of the same plant species from non-polluted environments; and 3) a hyperaccumulator is regarded as a plant in which the concentrations of

heavy metal in the shoots are greater than that in soils. More than 75% hyperaccumulator plants accumulate Ni, and only five species to date has been identified for Cd hyperaccumulation.^[24] Ni has been found to reach the highest concentration in a tree endemic to the serpentine soil from New Caledonia *S. acuminata*, which accumulates up to 26% Ni (dry mass) in its latex.^[31] *Thlaspi calaminare* and *Phyllanthus serpentinus* were reported to accumulate 39,600 mg kg⁻¹ Zn and 38,100 mg kg⁻¹ Ni, respectively, in their leaves.^[32] About 25% of discovered hyperaccumulators belong to the family of Brassicaceae and, in particular, to genera *Thlaspi* and *Alyssum*. The majority of metal hyperaccumulating plant species discovered so far are restricted to tropical areas. Habit of these plants ranges from annual herbs to perennial shrubs and trees, and some species, such as *Sedum alfredii*, show the capacity of accumulating two or more elements.^[33] A list of hyperaccumulator plants obtained from different investigators^[6,30,34,35,36] is given below.

As: *Pteris vittata*, *Agrostis capillaris*, *Agrostiscastellana*, *Agrostis tenerrima*, and *Sarcosphaera coronaria*.

Cr: *Alyxia rubricaulis*, *Maytenus bureaviana*, *Maytenus pantheriana*, *Maytenus sebertiana*, *Garcinia amplexicaulis*, *Austromyrtus bidwillii*, *Eugenia clusioides*, *Eugenia* sp., *Beaupreopsis paniculata*, *Macadamia angustifolia*, *Macadamia neurophylla*, *Astragalus stanleya*, *Haplopappus*, and *Machaeranthera*.

Co and Cu: *Pandiaka metallorum*, *Anisopappus davyi*, *Cyanotis longifolia*, *Ascolepis metallorum*, *Bulbostylis pseudoperennis*, *Phyllanthus williamiioides*, *Crotalaria cobalticola*, *Vigna dolomitica*, *Aeollanthus subacaulis* var. *linearis*, *Haumaniastrum robertii*, *Eragrostis racemosa*, *Actiniopteris* sp., *Buchnera henriquesii*, *Sopubia neptunii*, *Triumfetta dekindtiana*, *Triumfetta welwitschii* var. *descampii*, and *Xerophyta retinervis* var. *equisetoides*.

Cu: *Clerodendrum infortunatum*, *Croton bonplandianus*, *Geniosporum tenuiflorum*, *Tephrosia villosa*, and *Waltheria indica*.

Cd, Pb and Zn: *Arabidopsis halleri*, *Thlaspi caerulescens*, *Thlaspi brachypetalum*, *Thlaspi ochroleucum*, *Thlaspi cepaeifolium*, *Thlaspi praecox*, *Thlaspi stenopterum*, *Thlaspi tatrensiniuartia verna*, *Polycarpha synandra*, *Dichapetalum gelonioides*, *Armeria maritime*, *Agrostis tenuis*, *Arrhenatherum elatius*, *Festuca ovina*, *Rumex acetosa*, and *Viola calaminaria*.

Mn: *Vaccinium myrtillus*, *A. bidwillii*.

Ni: *Berkheya coddii*, *Pentacalia* (10 species), *Senecio* (9 species), *Alyssum* (52 taxa), *Bornmuellera* (6 taxa), *Cassia kleinii*, *Cochlearia aucheri*, *Crotalaria biflora*, *Evolvulus alsinoides*, *Hybanthus enneaspermus*, *Peltaria emarginata*, *Streptanthus polygaloides*, and *Thlaspi* (23 taxa).

Phytodegradation

Phytodegradation involves the chemical modification of the pollutants, usually by decomposing them into less

harmful products through the action of enzymes, acids, and other metabolic by-products. Degradation of organic pollutants in the rhizosphere can be enhanced directly by root-derived enzymes and indirectly by aeration due to root activity, microbial activity, and modified microbial composition due to C inputs and metabolic precursors (e.g., phenolics) exuded by roots. These substances can attack the pollutant through enzymatic and metabolic activities and can produce unspecific effects of changes in pH, osmotic potential, redox potential, partial pressures of oxygen/carbon dioxide (O₂/CO₂) in soil, etc. Thus, phytodegradation mainly remediates organic pollutants in soils and sediments and can occur in three different manners:

1. Organic pollutants are decomposed and converted into less harmful substances in soil by metabolites in root exudates. For example, TCE can be degraded in soil by the roots of hybrid poplars (*Populus trichocarpa* × *Populus deltoides*) and Eastern cottonwoods (*P. deltoides*). These phreatophytic plants exude dehalogenase enzyme that transforms or mineralizes TCE. Important rhizodegrader plants include *Elymus canadensis*, *Festula arundinacea*, *Festula rubra*, *Lolium prene*, *Lotus corniculatus*, *Melilotus officinalis*, *Panicum virgatum*, *Trifolium pretense*, *Trifolium repens*, *Helianthus annuus*, *Pteris vittata*, *Betula pendula*, *Illex* spp., *Morus rubra*, *Populus* spp., *Salix* spp., etc.^[6]
2. Plants absorb contaminants through roots and convert them into harmless substances within the plant tissue. For example, the phreatophytic plants, hybrid poplars and Eastern cottonwood, can accumulate TCE in their tissues and metabolize them converting it all the way to normal end points such as CO₂ and salts. Some plants contain enzymes that can breakdown and convert ammunition wastes, chlorinated solvents such as TCE, and other herbicides. The enzymes are usually dehalogenases, oxygenases, and reductases. Pilon-Smits^[37] reported the mechanism of degradation of xenobiotics, upon entering the symplast, as the modification through oxidation, reduction, and/or hydrolysis reactions followed by conjugation with glutathione (GSH), sugars, or organic acids. The latter step renders them more soluble and probably facilitates their subsequent binding to enzymes, transporters, and other relevant proteins. Conjugated xenobiotics are then sequestered as part of insoluble cell wall polymers or in cellular compartments such as vacuoles, where they can be metabolized further ideally to CO₂ (mineralization). Uptake and translocation of a POP molecule in plant tissues depend on the pollutant's concentration in the soil solution, its ability to enter the root system, and the rate of transpiration in the plant.^[38] Since most POPs are irreversibly held on soil particle surfaces and usually very little desorption occurs, only low concentrations of POPs are present in soil solution. So, the

efficacy of phytoremediation of POPs is limited by the bioavailability of the pollutant that depends on the physical and chemical properties of their own as well as those of the soil. As uptake of POPs and their translocation within the plant tissue occurs usually in passive processes, removal of POPs from soil in significant quantity is possible only by increasing their solubility. Cyclodextrins amendments have been used to increase the elution of organic compounds from soils.^[39]

3. Biochemical breakdown of organic contaminants is caused by microorganisms stimulated by rhizosphere activity (often called rhizodegradation which is a slow process).^[40] Plant roots release, in their vicinity in soil, a wide variety of organic compounds that can have a very important influence, positive and negative, on growth of other plants and microorganisms and on their activities. Changes in microbial populations following exudate inputs may selectively increase the proportion of pollutant degraders in the soil. But it is more commonly observed that the proportion of pollutant degraders remains unchanged in polluted soil receiving root exudates, even when degradation is enhanced.^[41] The compounds in root exudates include sugars dominated by glucose, proteinogenic amino acids, organic acids, flavonols derivatives of lignin, coumarins, aurones, glucosinolates, anthocyanins, indole compounds, fatty acids, sterols, allomones, proteins and enzymes, etc. Many of these compounds stimulate the growth of microorganisms in the rhizosphere and accelerate the degradation of xenobiotics. Prolific microbial growth due to various root exudates in the rhizosphere provides improved degradation.^[16] Many of the soil contaminants are petroleum hydrocarbons (PHCs) derived from crude oil or refined petroleum products. Trees and herbaceous plants are widely and effectively used in the remediation of PHC-contaminated soils.

Rhizofiltration

The absorption of contaminants, usually metals, from aquatic environments by plants is known as rhizofiltration. Rhizofiltration uses plant roots to absorb heavy metals from polluted effluents, extracted groundwater, surface water, and wastewater with low contaminant concentrations of metals like Pb, Cd, Cu, Ni, Zn, and Cr.^[42] Rhizofiltration can partially treat industrial discharge, agricultural runoff, or acid mine drainage. Rhizofiltration can be employed to treat surface waters used for irrigation. It occurs *in situ* or *ex situ* and species other than hyperaccumulators can also be used. Indian mustard has proven to be effective in removing a wide concentration range of Pb (4–500 mg L⁻¹).^[43] The technology has been tested in the field with U-contaminated water at concentrations of 21–874 µg L⁻¹,

and the treated U concentration reported by Dushenkov et al.^[44] was <20 µg L⁻¹ before discharge into the environment. Two natural divisions of plants are involved in rhizofiltration: 1) purely aquatic plants; and 2) plants with submerged root systems. Among aquatic plants, water hyacinth is the most popular in phytoremediation of polluted waters. It can grow fast and can accumulate nutrients as well as heavy metals. Water hyacinth can remove high amounts of Cd, Co, Ni, and silver and appreciable amounts of Pb and Hg.^[45] But water hyacinth has a number of problems that limit its commercial use. It has become a noxious weed in many countries. For example in Sudan, it has completely covered a large area of the Nile River with a dense mat known as *Sudd*. Water hyacinth can grow only in tropical or warm temperate climate, which are frost free in winter. Other aquatic plant species that have been demonstrated to absorb high amounts of heavy metals from water include *Azolla* spp., *Elodea* spp., *Eichhornia crassipes*, *Lemna* spp., *Myriophyllum* spp., *Typha* spp., and *Vallisneria* spp. Removal of Pb by *Azolla pinnata* was demonstrated by Thayaparan et al.^[46] *Pistia stratiotes* has been found to accumulate very high amounts of heavy metals including Cr, Pb, and Ni. It is capable of growing fast and reproducing within the shortest possible time. It is an excellent agent of rhizofiltration of heavy metal from polluted waters.^[47] Several terrestrial plants including sunflower (*H. annuus*), Indian mustard (*Brassica juncea*), tobacco (*Nicotiana tabacum*), rye (*Secale cereale*), spinach (*Spinacia oleracea*), and corn (*Zea mays*) have been studied for their ability of rhizofiltration.^[17] As pollution in surface and groundwater is a great problem in many tropical, particularly Asian and temperate countries, and rhizofiltration is an important mechanism of remediating As from groundwater.

FACTORS AFFECTING PHYTOREMEDIATION

Phytoremediation is influenced by climatic, topographical, hydrological, and edaphological conditions including moisture, temperature, altitude, and soil type and the accessibility of agricultural equipments of the site to be cleaned. The efficiency of phytoremediation largely depends on the interaction of contaminants with plant roots, their transport to other plant parts, and their metabolism in the plant tissue. Depth and extent of the root systems of the plants used for phytoremediation are also important aspects in relation to their success of removal of pollutants. Soil contaminants are organic and inorganic chemical elements, compounds, and complexes, and rhizosphere action on them is affected primarily by their mobility. Their physicochemical characteristics such as solubility in water, molecular size, charge, vapor pressure, etc. and interactions with surrounding molecules determine their mobility and ease of remediation. Soil properties such as pH, texture, structure, and organic

matter contents are relevant in this context.^[48] Some of the metals are immobile in soils and their availability and phytoextraction rate are limited by solubility and diffusion to the root surface.^[49] One way to summarize many of the limitations of phytoremediation is that contaminants must be available to a plant and its root systems for their successful inactivation and eradication.^[37]

ENHANCEMENT OF PHYTOREMEDIATION

Often phytoremediation needs to be enhanced for which some agronomic practices and chemical amendments become necessary. Artificially guiding plant roots toward polluted zones, supplemental irrigation, fertilization, or root oxygenation can also be beneficial. Moreover, suitable plants can be selected or engineered for appropriate root architecture and metabolic capability.^[50] A key to effective phytoremediation, especially phytoextraction, is to enhance metal phytoavailability and to sustain adequate metal concentrations in the soil solution for plant uptake. Several chemical amendments, including some chelating agents and acids, can increase mobility of contaminants. Chelating agents form metal chelate complexes and prevent precipitation and sorption of the metals in the soil. Chelates can also bring metals into solution through desorption of sorbed species and dissolution of precipitated compounds. Additionally, the application of certain chelates to the soil increases the translocation of heavy metals into the shoots. Luo et al.^[51] reported that the application of chelating agents increased the root-to-shoot ratios of the metals Cu, Pb, Zn, and Cd in *Z. mays* and *Phaseolus vulgaris*. Common chelating agents for phytoextraction of metals include *trans*-1,2-diaminocyclohexane-*N,N,N',N'*-tetraacetic acid (CDTA), *N*-(2-hydroxyethyl)iminodiacetic acid (HEIDA), *N*-hydroxyethylenediaminetriacetic acid (HEDTA), diethylenetriaminepentaacetic acid (DTPA), ethyleneglycol-bis(β -aminoethyl ether) (EGTA), *N,N,N,N'*-tetraacetic acid (EGTA), or ethylenediaminedio-hydroxyphenylacetic acid (EDDHA). Some organic acids, including the malic, citric, and nitriloacetic acids,^[52] have been suggested useful for enhancing phytoextraction of metals. Many reports indicate that ethylenediaminetetraacetic acid (EDTA) and SS-ethylenediaminedissuccinic acid (EDDS) successfully improve heavy metal uptake by plants.^[53] Marques et al.^[53] reported that EDTA addition to contaminated soils increased the accumulation of Zn by *Solanum nigrum* by 231% in leaves, 93% in stems, and 81% in roots. Similarly, EDDS application enhanced the accumulation in leaves, stems, and roots up to 140%, 124%, and 104%, respectively. The decrease in soil pH following biosolid application is the major reason for the greater mobility of heavy metals in biosolid-treated soil. Moreover, dissolved organic matter can facilitate metal transport in soil by acting as a carrier through formation of soluble metal-organic complexes.

GENETIC ENGINEERING FOR PHYTOREMEDIATION

In genetic engineering of plants, a foreign piece of DNA, from any organism ranging from bacteria to mammals, or other plants, is stably inserted into the genome of a cell, which is regenerated into a mature transgenic plant. When the transformed plant is propagated, the foreign gene is inherited by its offspring. Likewise, desirable genes involved in metal uptake, translocation, and sequestration can be transferred into suitable plants for improved phytoremediation traits. The ideal plant species to engineer for phytoremediation should be capable of fast growth and high biomass production, sufficiently hardy and competitive in the climate where it is to be used, has a good phytoremediation capacity to start with, has a widespread, highly branched root system and ability to accumulate metals in the aboveground parts, and is amicable for genetic transformation.^[54] Research on hyperaccumulator species from the Brassicaceae, including *Allysum bertolonii*, *Allysum murale*, *A. halleri*, and *T. caerulescens*,^[55] and the multielement accumulator *B. juncea* has greatly benefited from the availability of functional genomics tools already utilized in *Arabidopsis thaliana* research.^[56] *A. thaliana* L. and tobacco (*N. tabacum* L.) have been genetically modified with bacterial organomecurial lyase (*MerB*) and mercuric reductase (*MerA*) genes.^[13] These plants absorb elemental Hg(II) and methyl Hg from the soil and release volatile Hg(0) from the leaves into the atmosphere. Thus, species of Brassicaceae have become model organisms for the molecular genetic analysis of metal hyperaccumulation and tolerance. Possible genetic manipulation for phytoremediation could be achieved in the following areas:^[54] 1) metallothioneins—the transfer of human metallothionein gene in tobacco resulted in plants with enhanced Cd tolerance and pea metallothionein gene transfer to *A. thaliana* resulted in increased Cu accumulation; 2) phytochelators—transgenic *B. juncea* overexpressing different enzymes involved in phytochelatin synthesis could extract more Cd, Cr, Cu, Pb, and Zn than wild plants; 3) organic acids—the overexpression of citrate synthase has shown to promote enhanced Al tolerance; 4) phytosiderophores—the overexpression of nicotianamine aminotransferase in rice resulted in the overproduction of Fe-chelator deoxy mugineic acid, a phytosiderophore, and consequently promoted a more efficient growth in Fe-deficient soils; 5) ferritin—the overexpression of Fe-binding protein ferritin has shown to increase up to 1.3-fold higher the Fe level in tobacco leaves;^[57] 6) metal transporters—transfer of Zn transporter (ZAT) gene from *Thlaspi goesingense* to *A. thaliana* resulted in twofold higher Zn accumulation in its roots; 7) alteration of metabolic pathways—transfer of *Escherichia coli* ars C and γ -ECS genes to *Arabidopsis* plants resulted in individuals that could transport oxyanion arsenate to aboveground tissues, reduce to arsenite, and sequester it to thiol peptide complexes;

8) alteration of oxidative stress mechanisms—overexpression of GSH-S-transferase and peroxidase in *Arabidopsis* plants resulted in enhanced Al tolerance; and 9) alteration in biomass—increasing phytohormones synthesis can increase biomass of transgenic plants.

CONCLUSIONS

Environmental pollution is a serious global problem. Organic and inorganic contaminants, particularly POPs and heavy metals, which are released into the environment through anthropogenic activities can reach toxic and lethal concentrations in soil, water, and air. Their remediation from polluted sites is, therefore, a dire necessity. Of the variety of techniques available at present, phytoremediation is environmentally, socially, aesthetically, and economically effective, safe, and universally acceptable for low-level pollution of soil and water. Many indigenous plants can be used and explored, and some plants can be genetically modified for improving their remediation capability. Phytoremediation is effective when the contaminants become available to plant roots; hence some sort of enhancement may be needed. Several chemical amendments, including some chelating agents and acids, are used for enhancement. Small-scale farm holders may be familiarized with these techniques of phytoremediation.

Plant Growth: Oxygen Diffusion Rate

Witold Stepniewski

Technical University of Lublin, Lublin, Poland

Abstract

Oxygen diffusion rate (ODR) is of importance because availability of oxygen to plant roots is a basic factor of soil productivity. A knowledge of the method of measurement of ODR helps one to evaluate oxygen requirements of particular plant species at different stages of their development. Moreover, this can be used as a diagnostic tool to assess the oxygen availability in a particular soil under definite conditions.

INTRODUCTION

What Is Oxygen Diffusion Rate (ODR)?

ODR is an electrochemical method of assessment of soil oxygen availability to plant roots. It is based on the analogy of oxygen uptake by plant roots and by platinum wire electrode placed in the soil.

Concept and Principle of the Method

As early as 1926, Hutchins^[1] expressed a conviction that it is not so much the concentration of oxygen in the soil as the possibility of its uptake by plant roots that determines the plant response to the oxygen conditions in the soil. This idea was realized in 1952 by Lemon and Erickson,^[2] who designed an electrode simulating oxygen uptake by plant roots. An important role in this concept is played by the presence of water or exudate films on the root surface. These films, due to the low diffusion coefficient of gases in water, form a significant obstacle in the path of oxygen from the soil air to the root.^[2,3]

The principle of this method consists in the measurement of the amount of oxygen diffusing onto the surface of a platinum wire electrode (usually 0.5–1.0 mm in diameter and several millimeter in length), where it is reduced electrochemically to hydroxide ions or water.^[2,3] In practice, the value of ODR is determined on the basis of measurement of the diffusion current intensity on a platinum electrode, which is negatively polarized in order to provide specific conditions for the reduction of oxygen molecules only. The platinum wire is therefore a model of oxygen absorbing root, and the intensity of oxygen flux to the electrode indicates the maximum amount of oxygen that would be available for a plant root placed in the same spot as the electrode.

SOIL PARAMETERS AND ODR

The ODR index reflects comprehensively the soil oxygen availability, as it comprises the effect of all the factors such as respiration, moisture, and the physical particle arrangement that influence the concentration of oxygen in soil air, the effective thickness of the water films around the roots, and their diffusion characteristics.

The ODR values in soils vary, most frequently, within a range from 0 to 200 $\mu\text{g m}^{-2} \text{sec}^{-1}$ (see Figs. 1–3). They decrease with soil-moisture content and with soil compaction, and they increase with moisture tension, with air-filled porosity of the soil, and with oxygen content in soil air.^[4] Due to this, a decrease in ODR is expected usually with depth, especially just above the groundwater table. An example of the relationship of ODR on soil-moisture tension and bulk density is presented in Fig. 1.

Beyond the soil moisture content and bulk density, the value of ODR is related to many other soil parameters. The dependence on the gas diffusion coefficient^[5] is shown in Fig. 2. The relationship with air permeability of the soil^[5] is illustrated in Fig. 3. The value of ODR is also related to redox potential^[4] and to dehydrogenase activity.^[6]

ODR AND PLANT RESPONSE

Seedling Emergence

In a typical relationship between plant emergence and ODR^[4] starting with the highest values of ODR, initially a plateau range is observed with insignificant differentiation in emergence. Then, after reaching a certain limiting value, a significant decrease in the final emergence percentage in comparison with the germination capacity is observed. Thereafter, there is a rapid linear decline in

Fig. 1 ODR vs. bulk density and soil moisture tension in a loamy textured Chernozem Rendzina soil.

Source: Adapted from Stepniewski.^[7]

the number of emerging plants as the ODR decreases, this number falling to zero at the critical ODR. It was found that the limiting values for the plant emergence range from 25 to 100 $\mu\text{g m}^{-2} \text{sec}^{-1}$ and the critical values from 7 to 40 $\mu\text{g m}^{-2} \text{sec}^{-1}$.^[4]

Root Response

Root tissue is that part of a plant which is subjected first to oxygen deficiency or anoxia, and the consequence is a decrease of the root biomass at low ODR.^[4,8] It was confirmed that wheat-root population in soil^[9] increased

Fig. 2 ODR vs. relative gas diffusion coefficient D/D_0 in soil, where gas diffusion coefficient D of a gas relates to the soil and D_0 to the atmospheric air at the same temperature and pressure conditions. Collective data for 24 soil horizons of six different soil profiles from Hungary.

Source: Adapted from Stepniewski.^[5]

Fig. 3 ODR vs. air permeability (k) of the soil. Collective data for 24 soil horizons of six different soil profiles from Hungary.

Source: Adapted from Stepniewski.^[6]

linearly with ODR in the interval from 40 to 60 $\mu\text{g m}^{-2} \text{sec}^{-1}$ more than fivefold. Root-elongation rate of three desert shrubs also increased with ODR in the interval 30–90 $\mu\text{g m}^{-2} \text{sec}^{-1}$.^[10] It was found that for numerous grass species critical ODR value is below 10 $\mu\text{g m}^{-2} \text{sec}^{-1}$.^[4] In case of lowland rice, root porosity decreased from 23% at ODR < 20 $\mu\text{g m}^{-2} \text{sec}^{-1}$ to about 5% at ODR as high as >100 $\mu\text{g m}^{-2} \text{sec}^{-1}$.^[4]

Shoot Response

Shoot response to root hypoxia expressed by the ODR values has been studied intensively. As it was found, the uptake of water by orange seedling was 2 to 3 times higher at ODR > 60 $\mu\text{g m}^{-2} \text{sec}^{-1}$ as compared to that at ODR < 40 $\mu\text{g m}^{-2} \text{sec}^{-1}$.^[11] Another effect is the closure of stomata and an increase of stomatal diffusive resistance at ODR below 30 $\mu\text{g m}^{-2} \text{sec}^{-1}$.^[8,12] An obvious decrease of the shoot biomass observed by numerous authors for plants such as sorghum, cabbage, soybean, maize, and potato^[4] is the result of physiological disorders. These disorders comprise appearance of ethanol observed in xylem exudate of tomato plants at ODR below 20 $\mu\text{g m}^{-2} \text{sec}^{-1}$,^[13] reduced chlorophyll content,^[8,14] reduced net photosynthetic rate,^[15] reduced carotenoid and protein content,^[15] and reduced activity of superoxide dismutase related to the plant defense system.^[8]

The observed changes in the mineral composition of the plants result from combined effect of redox transformations of nutrients in the soil as well as from the modification of metabolic processes in the plant tissues. Thus, the concentrations of zinc, copper, and boron (B) in the soybean seeds and shoots tended to decrease at ODR values below 20 $\mu\text{g m}^{-2} \text{sec}^{-1}$, while manganese (Mn) and iron concentrations, in turn, tended to increase under such conditions^[16] due to increased availability of the two

latter elements. These opposite tendencies lead to a more distinct differentiation of their ratios, demonstrated for Mn/B ratio.^[17]

These and previously reviewed papers^[4] indicate that plants are differentiated with their response to low ODR values, and the limitation of the growth occurs usually in the range 35–70 $\mu\text{g m}^{-2} \text{sec}^{-1}$.

CONCLUSION

It has been documented that an ODR value depends on numerous soil parameters such as water content, bulk density, air-filled porosity, gas diffusion coefficient, air permeability, and oxygen concentration in soil air, and that it affects redox potential and dehydrogenase activity. It was also shown that plant parameters such as emergence percentage, root population, root elongation, biomass production, as well as numerous physiological parameters like chlorophyll, carotenoids, proteins, superoxide dismutase, ethanol, microelements, stomatal diffusive resistance, and net photosynthesis are related to ODR values.

Plant Nutrients

Volker Roemheld

Institute for Plant Nutrition, University of Hohenheim, Stuttgart, Germany

Abstract

Great progress in the knowledge on requirements and the function of plant nutrients for plant growth has initiated the recognition of the use of mineral fertilizers in the late 19th and the early 20th centuries. Considering a still growing world population, further improvements and achievements in an adequate supply of needed plant nutrients as organic or mineral fertilizers, together with innovative application techniques with maximum use efficiency, will be required in the future.

INTRODUCTION

In the late 19th century, the importance of mineral elements for the growth and development of plants was established, particularly, by Carl Sprengel (1787–1859) and Justus von Liebig (1803–1873). In the following decades, mineral elements were classified as essential (“plant mineral nutrients”), non-essential, and beneficial elements by the strict criteria that were laid down by Arnon and Stout (1939).

As a consequence of the great progress in understanding the function of these mineral nutrients in plants, the use of increasing amounts of mineral fertilizers in agriculture was initiated. Further progress in use of mineral nutrients for improvement in crop yield and crop quality is required to match the need of a worldwide growing population.

PLANT NUTRIENTS

Historical Retrospect

Although the beneficial effect of adding mineral elements (e.g., plant ash and lime) as soil fertilizers for growth promotion had been known for a long time, the first who compiled and summarized the importance of distinct mineral elements were Sprengel (1787–1859) and von Liebig (1803–1873).^[1]

In particular, von Liebig’s well-known textbook *Die Chemie in ihrer Anwendung auf Agricultur und Physiologie*^[2] rose awareness of farmers and scientists of plant mineral nutrients. Thus, as a consequence of his achievements, the use of large amounts of potash, superphosphate, and later inorganic nitrogen in agriculture and horticulture was initiated to improve plant growth. But also investigations into the essentiality of the various mineral elements were undertaken by different scientists at the end of the 19th century to support von Liebig’s “mineral element theory.”

From those investigations into the mineral composition of different plant species grown on various substrates, it was obvious that the presence or the concentration of a distinct mineral element in plant tissue is not a criterion for essentiality. Beside the essential, due to a limited selectivity in nutrient uptake, non-essential and even toxic elements can also be taken up by plant roots. On the other hand, improved analytical methods and better purification of chemicals in the 20th century resulted in discovery of further microelements essential for plant growth. This is reflected in the timescale of discoveries of the essentiality of the various micronutrients (Table 1). Nickel, with one of the lowest required plant tissue concentration, has been identified as an essential element by Brown, Welch, and Cary as late as 1987.^[3] As a consequence of continuous improvements in analytical techniques, it can be expected that further mineral elements at very low concentrations will be discovered as micronutrients for plant growth.

Definition of Plant Nutrients

The inorganic elements that are exclusively required by higher plants to maintain life and growth are called *essential mineral elements* or *mineral nutrients* (plant nutrients) by Arnon and Stout.^[4] These authors laid down the following three criteria for an element to be considered essential:

1. In the absence of the distinct mineral element, the life cycle could not be completed.
2. The function of one mineral element cannot be replaced by another mineral element.
3. The mineral element must be directly involved in the plant metabolism, either as component of a plant constituent such as plasma membrane or enzymes or required for a distinct metabolic step in enzymatic processes.

Table 1 Mineral nutrients separated for macro- and micronutrients, average concentrations in plant shoot dry matter for adequate growth and discovery of the essentiality of micronutrients for higher plants.

Element	Shoot tissue concentration ($\mu\text{mol g}^{-1}$ dry wt)	Year of discovery
Macronutrients		
Nitrogen	1000	
Potassium	250	
Calcium	125	
Magnesium	80	
Phosphorus	60	
Sulfur	30	
Micronutrients		
Chlorine	3.0	1954
Boron	2.0	1923
Iron	2.0	1860
Mn	1.0	1922
Zinc	0.3	1926
Copper	0.1	1931
Nickel	0.001	1987
Molybdenum	0.001	1938

Source: Adapted from Marschner.^[5]

According to these rather strict criteria, 14 mineral elements have been classified as essential or plant mineral nutrients (Table 1). Other mineral elements that can replace mineral nutrients in some of their less specific functions, such as sodium in the maintenance of osmotic pressure, or that can compensate for toxic effects of other elements [e.g., manganese (Mn)] such as silicon, are not essential, but can be described as beneficial elements. This definition is particularly true for the mineral element selenium. There are increasing indications that this mineral element is involved in metabolic processes of stress resistance. It has been shown that selenium at low dosage can enhance antioxidative power and diminish lipid peroxidation due to enhanced activities of glutathione peroxidase and superoxid dismutase.^[6] This would mean that selenium is required as beneficial element under adverse growth conditions such as drought, high temperature, or ultraviolet irradiation stress.

Classification and General Function of Plant Nutrients

The 14 plant mineral nutrients can be divided into two groups: six macronutrients and eight micronutrients. In general, plant tissue concentrations of macronutrients are distinctively higher than those of micronutrients (Table 1). However, such division of plant nutrients into these two groups is not always that clear. In various cases, the

differences between macro- and micronutrients are decisively less pronounced as indicated in Table 1. For example, tissue concentrations of iron and Mn can be sometimes nearly as high as concentrations of macronutrients sulfur or magnesium.

Hence, from a different viewpoint, a physiological or biochemical classification of plant mineral nutrients into four groups has been proposed by Mengel and Kirkby.^[7] The first group includes the major constituents of the organic plant material: nitrogen and sulfur. Both elements are involved in enzymatic processes and assimilated by oxidation–reduction reactions. Phosphorus, boron, and silicon constitute the second group of essential elements and show similar biochemical behavior such as the formation of esters with native alcohol groups with importance in stabilizing cell walls and/or biomembranes.

The third group of plant nutrients is made up of potassium, calcium, magnesium, Mn, and chloride. Besides more specific reactions such as conformation of enzyme proteins, bridging of reaction partners, and controlling membrane permeability, they perform some non-specific functions like establishing osmotic potential and balancing anions.

The plant nutrients of the fourth group, namely iron, copper, zinc, and molybdenum, are all predominately present as chelates in plants, often incorporated in prosthetic groups, and enable electron transport by valency change.

Besides these abovementioned essential mineral elements, the beneficial mineral elements sodium and silicon and also chlorine and selenium have to be considered as an additional group. Cobalt is also well documented as an essential element for certain higher plants. This is closely related to biological nitrogen fixation, as this mineral nutrient is a constituent of the vitamin B₁₂.^[5] For the same plant species supplied with adequate inorganic (NO_3^- and NH_4^+) or organic nitrogen forms (amino acids), cobalt is not essential or beneficial.

It will always be difficult to generalize which mineral elements are essential for plant growth. In this way, silicon and sodium are established as essential only for some higher plant species. According to Epstein,^[8] silicon is essential for rice and other wetland grasses, sugar cane, and species of the *Equisetaceae* family. This does not exclude the beneficial effect of silicon for most plant species, e.g., in the suppression of plant diseases and pests.^[5] On the other hand, sodium at relatively low concentrations is essential for some C₄ plant species excluding *Zea mays*.^[9] The function of sodium as an essential mineral element in C₄ plants such as *Panicum miliaceum* (NAD⁺ malic enzyme type) has been shown from experiments with isolated chloroplasts. In *P. miliaceum*, sodium enhances pyruvate uptake, which indicates a sodium/pyruvate cotransport through the membrane into the chloroplast, driven by a light-stimulated Na⁺ efflux pump.^[10]

Other Aspects

Besides essentiality or beneficial functions for growth and development of plants, there is an increasing interest in mineral nutrients from the viewpoint of quality for human food. Particularly, iodine, iron, zinc, and selenium are widespread limiting mineral nutrients for humans in specific regions;^[11] e.g., in an area with a diet based mainly on rice (Southeast Asia) or on millet (Africa), iron deficiency is a serious problem for children. Supreme effort is required to enhance iron tissue concentration and bioavailability in these crop plants by breeding and modern molecular approaches to overcome this nutritional problem.

CONCLUSION

Great progress in the knowledge on requirements and function of plant nutrients for plant growth has initiated the recognition of the use of mineral fertilizers in the late 19th and early 20th centuries. von Liebig's text book *Die Chemie in ihrer Anwendung auf Agricultur und Physiologie* was a milestone for the importance of mineral nutrients for plants at this time.

Considering a still growing world population, further improvements and achievements in an adequate supply of needed plant nutrients as organic or mineral fertilizers together with innovative application techniques with maximum use efficiency will be required in the future. Particularly, mineral nutrients like iodine, iron, and zinc have to be seriously considered for high-quality human food in regions with respective deficiency problems.

Plant Nutrients: Intensity, Quantity, and Buffer Power

Ram C. Dalal

Department of Science, Information Technology, and Innovation,
Queensland Government, Dutton Park, Queensland, Australia

Abstract

This entry is concerned with the relative contribution of the intensity, quantity, and buffer power and their interactions in nutrient availability to plants. For routine laboratory assessment of available plant nutrients in soil, we need to measure at least two of the three parameters of availability, i.e., quantity and buffer power, or quantity and intensity, so as to improve nutrient management of ecosystems. The laboratory data can then be utilized in nutrient uptake models, which also include kinetics and diffusion of nutrients as well as plant–soil interactions. It is imperative that we understand and appropriately measure the extent of availability of plant nutrients from soil and added sources such as fertilizers and manures, for efficient and economic use of nutrients and for minimizing environmental pollution.

INTRODUCTION

Plant nutrient availability in soil is dominated by soil solution phase processes such as hydrolysis, hydration, carboxylation, and oxidation–reduction reactions. In addition, microbes and plant roots, through their synthetic and metabolic activities, mediated by both intracellular and extracellular enzymes, affect these solution phase processes. These processes determine the activity of plant nutrient ions in the soil solution and, in dilute soil solution, nutrient ion activity may be taken as concentration of nutrient or nutrient intensity factor (C_i). Sorption, desorption, precipitation, dissolution, complexation, and ion exchange with the nutrient on the solid phase provide quasi equilibrium with nutrient concentration in the soil solution. The concentration of nutrient in the entire soil mass is the quantity factor (C_s). The change in intensity factor with a change in quantity factor—i.e., dC_s/dC_i —is the nutrient buffer power. Because growing plants continually remove nutrient from the soil solution (intensity), the measure of capacity of the solid (and solution) phase nutrient (quantity) to maintain nutrient concentration during its withdrawal by plants (buffer power) is important for continual nutrient supply for plant growth. This is presented in Fig. 1.

This entry is concerned with the relative contribution of the intensity, quantity, and buffer power and their interactions in nutrient availability to plants.

INTENSITY FACTOR

The initial concentration of a nutrient in soil solution may be obtained by soil solution displacement^[1] and by equilibrating in dilute salt solutions such as 0.01 M calcium chloride (CaCl_2) or 0.02 M potassium chloride.

The relationship between low concentration range of a nutrient and plant uptake is described by the following equation:^[2]

$$U = 2\pi r \alpha C_r \quad (1)$$

where U is the nutrient uptake by a unit m root segment, r is the radius of the root, C_r is the nutrient concentration at the root surface, and α is the root absorbing power. Diffusion and/or mass flow and root interception control the nutrient concentration at the root surface.

The nutrient uptake by mass flow is closely related to plant water uptake. In most soils, plant uptake of NO_3^- , Ca^{2+} , Mg^{2+} , and Cl^- is primarily governed by mass flow.^[1] Thus, increasing water influx increases proportionately nutrient supply by mass flow. For example, by increasing plant water transpiration from 106 L/kg of plant shoot to 444 L/kg of shoot increased Ca^{2+} uptake from 72.8 mg to 177.6 mg/pot.^[1] However, nutrient ions such as H_2PO_4^- , K^+ , and Zn^{2+} , which are strongly sorbed on soil surface, and usually low in soil solution, are primarily supplied to root surface by diffusion flow.

Nutrient concentration at the root surface cannot be measured directly. However, it can be estimated by using Fick's first law

$$F = -DA \frac{dC}{dx} \quad (2)$$

where F is the nutrient flux, dC/dx is concentration gradient, A is the area for diffusion, and D is the diffusion coefficient. The negative D means net nutrient movement from high concentration to low concentration. However, in dilute solutions D may be taken as constant over a range of concentrations in the soil solution.^[3]

For highly mobile nutrients such as NO_3 and Cl , $b \leq 1$; for these ions, b is insignificant in plant nutrient availability. For relatively immobile nutrients such as P and Zn , $b \geq 1$; significance of b in plant nutrient availability increases as its value increases.

Fig. 1 A diagrammatic representation of intensity factor, quantity factor, and buffer power.

Source: From R.C. Dalal, unpublished.

For strongly sorbed ions such as P and Zn^{2+} , initial nutrient concentration in the soil solution rarely meets plant nutrient demand. Thus, intensity factor alone does not sufficiently explain the relationship between nutrient concentration and plant nutrient uptake. For example, H_2PO_4^- activity or concentration in the soil solution is usually not related to grain yield or nutrient uptake^[4] except in the early stages of plant growth. Quantity factor becomes an important consideration for plant availability of these nutrients.

QUANTITY FACTOR

The plant available quantity of most cations is that measured by displacing cations from the exchange complex with a strong concentration of salt solution such as ammonium acetate, sodium acetate, or silver thiourea.^[5] For micronutrient cations (Fe , Mn , Zn , and Cu), complexation agents, such as ethylenediaminetetraacetic acid or diethylenetriamine pentaacetate (DTPA), have been used to reduce the precipitation and resorption of extracted cations from the soil solution.^[5]

Numerous methods are available for measuring the plant available quantity of phosphorus. These methods include extraction of P from soil by dilute and strong acids, dilute and strong alkali solutions, neutral salt solutions, and their combinations and iron oxide impregnated paper,^[6] isotopic exchangeable phosphate and ion-exchange resin,^[6] and electroultrafiltration.^[2]

The nutrient concentration of the quantity factor is 1–4 orders of magnitude greater than that of the intensity factor. For example, in 20 Australian soils, mean intensity of P was 0.03 mg/L (0.3 mg/kg), whereas mean quantity was 15 mg/kg (L value and Olsen P) or 30 mg/kg soil (Colwell P).^[6] Also, quantity of nutrients, such as P ,^[7]

K^+ , and Zn^{2+} , in soil often exceeds that taken up by plants in field conditions, although intensive cropping could remove as much quantities of P , K^+ , and Zn^{2+} as measured by the quantity factor.

The quantity factor for P , K^+ , and Zn^{2+} correlates better than the intensity factor with plant nutrient uptake. In 20 Australian soils, the intensity factor (0.01 M CaCl_2 P) accounted for only 19% each for the variation in P uptake at 35 and 150 days of wheat growth, while the quantity factor (Colwell P) accounted for 2 to 3 times more, 38 and 56% for the variation in P uptake at 35 and 150 days of wheat growth, respectively.^[4] Similarly, in eight Australian soils, the intensity and quantity factors accounted for 29 and 81%, respectively, for wheat grain yield in the field.^[4] This also applies to Zn^{2+} availability. For example, in 13 Vertisols, relative yield response to Zn application was better correlated with DTPA-extractable Zn (C_s), $r^2 = 0.69$, than soil solution Zn (C_i), $r^2 = 0.56$.^[8]

BUFFER POWER

The availability of nutrients to growing plants is not only influenced by nutrient intensity and the quantity but also by the ability of soil to replace the nutrients as plants take it up from soil solution. The effective diffusion of the nutrient to the root surface depends on the soil's buffer power for that nutrient, volumetric soil moisture, and the impedance factor. This is described by an adaptation of Eq. 2 to the soil system by the following equation:^[9]

$$D_e = D_1 \Theta f_1 \frac{dC_i}{dC_s} + R \quad (3)$$

where D_e is the effective diffusion coefficient of nutrient ion in soil, D_1 is the diffusion coefficient of ion in water, Θ is the volumetric soil water content, f_1 is an impedance factor or tortuosity factor that is measured using non-adsorbed ions such as Cl^- ions, C_i is the concentration of nutrient ion in the soil solution (intensity factor), C_s is the quantity of nutrient ion in the entire mass of soil (quantity factor), and R is the residual term accounting for diffusion through the adsorbed phase, which is probably negligible in neutral soils for most ions.

The nutrient buffer power, b , is the reciprocal of dC_i/dC_s , i.e.,

$$b = \frac{dC_s}{dC_i} \quad (4)$$

The nutrient buffer power, b , is measured from either an adsorption isotherm or desorption isotherm. In adsorption isotherm, simulating fertilizer application, known amount of nutrient is added to soil and the soil incubated for periods from minutes (exchangeable cations) to several months to attain quasi equilibrium between the

sorbed or exchangeable ions and those in the soil solution. At the end of the incubation period, the concentration of nutrient in the soil solution is measured and C_1 and C_s are calculated. Desorption isotherms are constructed from desorption of nutrient by an electrolyte, electro-ultrafiltration, or ion-exchange resin, simulating the nutrient uptake by roots.

For a narrow range in nutrient concentration, there is a linear relationship between C_s and C_1 , i.e.,

$$C_s = b_1 C_1 + a_1 \quad (5)$$

where b_1 is the distribution coefficient and a_1 is a constant. The buffer power, b , is calculated from the following equation:^[10]

$$b = \rho b_1 + \theta \quad (6)$$

where ρ is the bulk density and θ is the volumetric moisture content.

However, for a wide range in quantity and intensity, the relationship between C_s and C_1 is frequently described by the Freundlich isotherm:

$$C_s = k C_1^n \quad (7)$$

where k and n are constants, k is related to nutrient sorption capacity of the soil, and n is related to nutrient bonding energy to soil or curvilinearity between the corresponding C_s and C_1 values in a soil.

Langmuir isotherm has also been used to describe the relationship between C_s and C_1 values in a soil,^[4,11]

$$C_s = \frac{MBC_1}{1 + bC_1} \quad (8)$$

On differentiating with respect to C_1 , Eq. 8 becomes

$$\frac{dC_s}{dC_1} = \frac{MB}{(1 + bC_1)^2} \quad (9)$$

As $C_1 \rightarrow 0$, Eq. 9 becomes

$$\frac{dC_s}{dC_1} = MB \quad (10)$$

where M is Langmuir adsorption maximum, B is bonding energy term, and the product, MB , is the maximum buffering capacity.

For 20 Australian soils, the P buffer power varied from 32 to 364, except in one soil, an oxisol, which had the value of 3476.^[6] For 33 United States and Canadian soils, the values varied from 33 to 299.^[12]

The P buffer values are much lower, from 19 to 75, for Central European soils.^[3] For 14 Australian Vertisols, Zn buffer power varied from 217 to 790.^[8] The K buffer power varied from 142 to 592 for southern Indian soils.^[3] The relative importance of nutrient buffer power, intensity, and quantity factors is illustrated for a number of experiments in Table 1.

PERSPECTIVES

Other factors that affect nutrient availability from soil such as climate (temperature and moisture), pH, nutrient placement, soil biota, and plant type should also be considered along with the parameters of plant nutrient availability. For strongly sorbed ions, nutrient concentration in the soil solution is usually low. It is not determined routinely in soil testing laboratories. While quantity of the nutrient is routinely measured in soil testing services, accounting for the variation in plant nutrient uptake almost always improves by considering the soil's nutrient buffer power. Nutrient uptake models also include buffer power, so it should be widely measured. Optimal assessment of plant available nutrients from soil as well as by fertilizer applications is essential to ensure the efficient use of nutrients for economic food and fiber production while minimizing nutrient loss/pollution to the environment. While techniques for measuring buffer power, quantity, and intensity factors should be further refined, consideration of buffer power along with quantity/intensity factors^[13] will improve estimates and hence the efficient use of plant available nutrients from soil.

CONCLUSION

For routine laboratory assessment of available plant nutrients in soil, we need to measure at least two of the three parameters of availability, i.e., quantity and buffer power, or quantity and intensity, so as to improve

Table 1 Percentage of variation in nutrient uptake accounted for by intensity factor, quantity factor, and a combination of intensity or quantity and buffer power.

Nutrient	Intensity (C_1)	Quantity (C_s)	Buffer power (b)	C_1 and b	C_s and b	References
P	17	75	27	49	86	[4]
P	15	51	—	79	89	[4]

Zn	13	—	—	38	—	[3]
Zn	27	27	0.08	27	29	[8]

nutrient management of ecosystems. The laboratory data can then be utilized in nutrient uptake models, which also include kinetics and diffusion of nutrients as well as plant–soil interactions. It is imperative that we understand and appropriately measure the extent of availability of plant nutrients from soil and added sources such as fertilizers and manures, for efficient and economic use of nutrients and for minimizing environmental pollution.

Plant Nutrients: Sufficiency and Requirements

Kanwar L. Sahrawat

*International Crops Research Institute for the Semi-Arid Tropics (ICRISAT),
Panthacheru, India*

Abstract

The research on determining the nutrient sufficiency and nutrient requirements of plants is a prerequisite for the efficient use of purchased inputs of nutrients and for making the overall agricultural production more efficient through optimal use of plant nutrients. However, there have been problems in consistency of the results, which are greatly influenced by growing conditions and complex interactions among environmental, cultural, and genetic conditions. Despite these limitations, the knowledge of nutrient sufficiency and requirement is helpful in improving the prediction of plant growth and yield. A combination of soil and plant tests may be more effective in determining the nutrient sufficiency and requirements of crops. While soil tests are effective in determining the long-term nutrient requirement of crops, plant tests are necessary to diagnose and correct the nutrient deficiency of the crops.

INTRODUCTION

To meet the ever-increasing need for food, feed, and fiber, the production has to keep pace with the population growth. This can be achieved by enhancing the soil fertility and making crop production efficient through optimal use of plant nutrients. Assessment of the nutrient sufficiency and requirements is an integral component of research on efficient and rational use of plant nutrient inputs. The objective of this entry is to provide a concise summary of the major developments in the research on plant nutrient sufficiency and requirements. The emphasis is placed on the salient research results from field studies. Readers are referred to an excellent text by Black^[1] for detailed discussion and summary of the past research.

BACKGROUND INFORMATION

The need for food, feed, and fiber production is ever increasing because of the continuous, rapid population growth. The need is most pressing in the developing world.^[2] Apart from water shortages, soil infertility is the major constraint on the plant growth and yield in most of tropical regions. The increased crop production can be achieved through enhanced soil fertility.^[1] Soil fertility can only be sustained if the nutrients removed from the soil are replenished through addition. Also, crop production needs to be made efficient through optimal use of plant nutrients. Assessment of the nutrient sufficiency and requirements is an important component of research for efficient and rational use of nutrients from external sources.

Nutrient Sufficiency

Nutrient sufficiency or critical nutrient concentration, as more commonly termed, is a relative term because an absolute sufficiency cannot be determined. Nutrient sufficiency is a measure of nutrient concentration in the plant and is determined by plant analysis. It is preferably expressed as a range of concentrations rather than a single concentration. Sufficiency of a given nutrient lies between critical deficiency value and an excess or toxic concentration. Alternatively, nutrient sufficiency is the range of concentrations for which the yield reduction and nutrient stress symptoms are not taken into account.^[3] A critical deficiency concentration of a nutrient is the one that corresponds to a yield that is 10% below the maximum on the low side, and a critical toxicity concentration of a nutrient is the one that corresponds to a yield that is 10% below the maximum on the high side.^[4] It is perhaps more useful to consider critical concentration as the concentration that separates plants that would respond to addition of more nutrients from those that would not respond.^[5] For practical purposes, economic criterion would appear more appropriate and the critical nutrient concentration may be termed as critical economic concentration.^[6]

Nutrient Requirement

Nutrient requirement is the amount of nutrient required to achieve a yield target that is normally 90% of the maximum yield obtained under optimal nutrient regime. As for nutrient sufficiency, economic considerations are equally relevant for determining the nutrient requirements of various crop plants.^[1] Nutrient requirements include both external

and internal nutrient requirements. External nutrient requirement is the concentration in the growing medium, usually soil, while the internal requirement is the concentration in the plant tissue at a yield target, which is normally 90% of the maximum yield.

DETERMINING NUTRIENT SUFFICIENCY AND REQUIREMENTS

Soil and plant analyses are used for determining the nutrient requirements of crops, while plant analysis is used for establishing the nutrient sufficiency under well-defined conditions of experimentation and collection of soil and plant samples. Data on nutrient sufficiency range in plant tissue of selected grain crops^[7] for macronutrients are summarized in Table 1.

Since the early finding that the chemical composition of plants changes with the nutrient supplies, attempts have been made to use the elemental concentrations for evaluating nutrient requirements of crops. For historical developments covering the period up to 1990, the readers are referred to the excellent text entitled *Soil Fertility Evaluation and Control* by C.A. Black.^[1] The literature is briefly covered in this entry. Evidently, much research has been done in determining the concentrations of nutrient elements as indexes of the sufficiency of nutrient supplies for crop growth and for determining nutrient requirements.^[2,7,8]

A book entitled *Plant Analysis Handbook* by H.A. Mills and J.B. Jones, Jr.^[7] provides tables of interpretive plant analysis data for over 1000 individual horticultural, agronomic, and plantation crops. The publication provides data on sufficiency or critical concentration range for macro- and micronutrient elements for various crop plants where the deficiency, sufficiency, and toxicity concentrations have been established over a wide range of conditions in the

solution culture to field. In addition, survey range and survey average values for various nutrient elements are also presented for growing conditions under which the upper and lower limits of nutrient concentrations have not been as clearly defined as in the case of sufficiency range. Survey average value refers to the nutrient level found in healthy, normal plants without the presence of visual symptoms on the foliage showing deficiency or toxicity. Another comprehensive treatise on *Plant Analysis: An Interpretation Manual* edited by Reuter and Robinson^[8] is also an excellent source of information on nutrient levels for deficiency, toxicity, and sufficiency for temperate and tropical crops, pasture species, fruits, vines, nuts, vegetable crops, ornamentals, and forest plantations. The treatise discusses in detail the concepts and principles for interpreting plant analysis and describes nutrient deficiency and toxicity symptoms in the plant, apart from providing concentration ranges of nutrients covering the range from deficiency to toxicity.

The determination of nutrient sufficiency and requirements is based on the relationships with plant growth and yield. The nutrient elemental composition of the plant at optimal yield should approximate the nutrient sufficiency levels, expressed either as individual nutrient concentrations or ratios of the various nutrient elements.^[1,8] Before soil and plant tests can be used for determining nutrient sufficiency and requirements, appropriate standards should be developed through field experimentation.^[9] Field experiments are considered essential for calibration because standards developed under controlled conditions, e.g., greenhouse pots may not be representative of the real world situation and may not hold under field conditions. Using the primary standards developed under field conditions, the relative sufficiency and requirements of nutrients can be determined under non-experimental conditions. Although it is generally accepted that the determination of sufficiency requirements for nutrients leads to improved

Table 1 The range of sufficiency levels of N, P, and K in plant tissue for selected grain crops.

		Sufficiency range concentration (%)		
Crop growth stage	Plant part	N	P	K
Corn or maize (<i>Zea mays</i>)				
Prior to tasseling	Leaf below the whorl	3.00–3.50	0.25–0.45	2.00–2.50
Rice (<i>Oryza sativa</i> L.)				
Maximum tillering	Newest, fully developed leaf	2.80–3.60	0.10–0.18	1.20–2.40
Barley (<i>Hordeum vulgare</i> and <i>Hordeum distichon</i>)				
Emergence of head from boot	Whole tops	1.75–3.00	0.20–0.50	1.50–3.00
Sorghum (<i>Sorghum bicolor</i>)				
37–56 days after planting	Newest, fully developed leaf	3.20–4.20	0.13–0.25	2.00–3.00
Winter wheat (<i>Triticum aestivum</i>)				
Just before heading	Top two leaves	1.75–3.00	0.20–0.50	1.5–3.00
Spring wheat (<i>Triticum aestivum</i>)				
Emergence of head from boot	Whole tops	2.00–3.00	0.20–0.50	1.50–3.00

prediction of yields, it is emphasized that these values depend on the growing conditions.^[1]

Several equations, which are based on the response of crop yield or relative yield or growth to nutrient concentrations in soil or plant, have been proposed for determining the nutrient requirements of crops. Black^[1] provides an excellent historical perspective to the developments in research on the use of soil and plant tests for determining the nutrient requirements of crops. It is evident from the discussion that while qualitative aspects of nutrient status are useful and at times, especially in the past, was considered acceptable, no generally satisfactory system of testing plants for nutrient deficiencies has emerged. This is a major obstruction in the use of nutrient concentrations for determining requirements in a quantitative and consistent manner. The lack of consistency, however, is not entirely unexpected in view of the fact that the concentrations of various nutrient elements are determined by the total mass of the plant, which in turn is influenced by the growing conditions relative to environment, nutrient supply and interactions among various nutrient elements, and the genetics of the crop.

Soil characteristics greatly influence the use of soil tests for determining the nutrient sufficiency or critical concentration levels for various nutrient elements. For example, one study with grain sorghum under rainfed cropping on nearby Alfisol and Vertisol sites at the International Crops Research Institute for the Semi-Arid Tropics, Patancheru (India) showed that on the Vertisol site, 90% relative grain yield was obtained at 2.8 mg/kg Olsen extractable phosphorous (P) while on the Alfisol site, 90% relative grain yield was achieved at 5.0 mg/kg Olsen P.^[10] These results demonstrate that a single critical limit of available P does not hold true for sorghum on the two soil types under similar agroclimatic conditions and that the critical limit is lower for the clayey Vertisol with higher phosphate buffering capacity than the sandy Alfisol with lower buffering capacity.

Field study with upland rice on an Ultisol in the humid forest zone of Ivory Coast showed that the critical limit of Bray 1 P in the soil at 90% relative rice grain yield varied from 12.5 and 15.0 mg P/kg soil for the four cultivars tested. The critical or sufficiency value tended to be lower for the P-efficient rice cultivars.^[11] Using plant tissue P concentration as the criterion, the critical concentration of P in the whole rice plant tops at the tillering stage, in the 90% relative grain yield, was found to be 2 g P/kg for the four rice cultivars. It was indicated that while the rice cultivars differed in the external P requirement (concentration in the growing medium), they did not differ in their internal P requirement (concentration in the plant tissue).^[11,12] In these field experiments, a significant linear relationship was observed between total P uptake in the biomass and rice grain or rice straw yield.^[12]

Sahrawat et al.^[13] provided results on the calibration of plant P test for predicting sorghum grain yield under rainfed

cropping of a Vertisol site (Typic Haplustert) in the semi-arid zone of India. Despite variability in the rainfall received during the 3 years of field study, the leaf (newest, fully developed leaf at 50% flowering stage of the crop) P concentration was found to be linearly related to grain yield (r^2 varied from 0.724 to 0.993). The relationships between leaf P and sorghum yield during the 3 years of study were described by the following equations:

In 1987

$$\text{Grain yield (t/ha)} = 4.057 + 28.300 \text{ leaf P (\%)} r^2 = 0.993 \quad (1)$$

In 1988

$$\text{Grain yield (t/ha)} = -7.693 + 50.0085 \text{ leaf P (\%)} r^2 = 0.724 \quad (2)$$

In 1989

$$\text{Grain yield (t/ha)} = -3.414 + 21.787 \text{ leaf P (\%)} r^2 = 0.979 \quad (3)$$

The critical or the sufficiency leaf P concentration at 90% of the maximum yield was found to be about 2.5 g P/kg (Fig. 1). Phosphorus content in the grain was not significantly correlated to yield. Two important points emerged from this study: 1) linear relationship between leaf P and yield over a range of applied P and 2) the Cate and Nelson split method^[14] of graphic presentation of relationship between leaf P and relative sorghum grain yield was found to be useful and had the practical

Fig. 1 Relationship between relative grain yield and P content in the index leaf (new, fully developed leaf) at flowering in sorghum grown on a Vertisol for 3 years (1987–1989). Each point represents an average value of four replications.

advantage in dividing the data into responsive and non-responsive populations.^[13]

SIMPLE MODELS FOR DETERMINING NUTRIENT REQUIREMENTS

Sahrawat^[15] evaluated two methods for determining the fertilizer phosphorus requirement (FPR) of sorghum. The first method used a simple method based on P uptake^[16,17] using the following equation:

$$\text{FPR} = (U_p - U_0)/\text{PRF} \quad (4)$$

where U_p is P uptake at a given yield, U_0 is P uptake from unfertilized soil, and PRF is the P recovery fraction of applied P. The parameters U_0 , U_p , and PRF were determined in a three-year field experiment with sorghum grown on a calcareous Vertisol site under rainfed conditions. The second method, proposed by the author, was based on the P applied, P uptake, and grain yield relationships. First, P uptake at a given sorghum yield was determined from the relationship between total P uptake and grain yield. The amount of fertilizer P applied for the given P uptake and grain yield was then determined from the relationship between P applied and P uptake. Based on 3 years results, it was found that the fertilizer P applied and total P uptake by sorghum were significantly and linearly related, which is described by regression Eqs. 5 and 6

$$\begin{aligned} \text{P uptake (kg/ha)} &= 1.67 + 0.200 \text{ P applied (kg/ha)} \\ (r^2 &= 0.97; n = 12) \end{aligned} \quad (5)$$

Total P uptake by the crop, in turn, was closely linearly related to sorghum grain yield and described by the following regression equation:

$$\begin{aligned} \text{P uptake (kg/ha)} &= 0.51 + 2.62 \text{ grain yield (t/ha)} \\ (r^2 &= 0.95) \end{aligned} \quad (6)$$

There was a close agreement between the observed values of FPR and the predicted values determined by the two methods. These results suggested that the simple models based on P uptake could be utilized for determining the nutrient requirements of crops.

Evaluation of the two methods described, for determining the fertilizer P requirements of upland rice cultivars grown for two seasons (1992–1993) under a range of applied P on an Ultisol site in the humid forest zone of Ivory Coast, showed that there was a good agreement between the observed values of FPR and the predicted values of FPR that were determined by the two methods. This indicates the usefulness of these simple methods based on P uptake for determining the P requirements of crops.^[18] As observed for sorghum, fertilizer P applied and P uptake and grain yield and P uptake by four upland rice cultivars were significantly and linearly related. Overall, the results

obtained with upland rice on an Ultisol site in the humid forest zone and sorghum on a Vertisol site in the semiarid tropical zone indicate a wide applicability of these simple models for determining P requirements of crops and merit further evaluation.

It was further indicated that using the Cate and Nelson split method,^[14,19] of graphic presentation of relationships between P applied and relative rice grain yield or between P uptake and relative yield provided a simple procedure for determining the P requirement of rice.^[18]

The author's unpublished results showed that a significant and linear relationship exists between fertilizer nitrogen (N) (as urea) and N uptake, and between grain yield and N uptake for lowland rice cultivars grown under irrigated conditions on Alfisols in central Ivory Coast. It was further indicated that these relationships could be used for determining the N requirements of lowland rice cultivars.

In a study, Pathak et al.^[20] used the Quantitative Evaluation of Fertility of Tropical Soils (QUEFTS) model^[21] for estimation of N, P, and potassium (K) requirements and fertilizer recommendations for targeted yields of wheat in India. The model considers the interactions of N, P, and K, and climate adjusted potential yield region wise in the country. Published data from field experiments conducted between 1970 and 1998 across the wheat-growing environments of India, covering a wide range of soils and climatic conditions, were used to capture the environmental variability effects on wheat yield. The relationships between soil's inherent N supply and soil organic carbon, P supply and Olsen extractable P in soil, and K supply and ammonium acetate extractable soil K were established. The results showed that required N, P, and K accumulation in the plant biomass for 1 t grain yield was 23.1, 3.5, and 28.5 kg, respectively. The observed yields of wheat with different amounts of N, P, and K were in agreement with the values predicted by the model, indicating that the QUEFTS model can be used for determining nutrient requirements and fertilizer recommendations for wheat production.

CONCLUSION

The research on determining the nutrient sufficiency and nutrient requirements of plants is a prerequisite for the efficient use of purchased inputs of nutrients and for making the overall agricultural production more efficient through optimal use of plant nutrients. However, there have been problems in consistency of the results, which are greatly influenced by growing conditions and complex interactions among environmental, cultural, and genetic conditions.^[1] Despite these limitations, the knowledge of nutrient sufficiency and requirement is helpful in improving the prediction of plant growth and yield. A combination of soil and plant tests may be more effective in determining the nutrient sufficiency and requirements of crops. While soil tests are effective in determining the long-term nutrient

requirement of crops, plant tests are necessary to diagnose and correct the nutrient deficiency of the crops.^[13,22,23]

There is need for future research to strengthen the use of models for determining nutrient requirements and fertilizer recommendations for crop production, as field experimentation is expensive and at times not practical.

Plastic Properties

Gunnar Kirchhof

New South Wales Department of Agriculture, Tamworth, New South Wales, Australia

Abstract

The application of a force to soil can result in an elastic, non-permanent, deformation that only lasts while the force is applied or a plastic, permanent deformation that persists after the load is removed. The latter may, or may not, result in a decrease in the soil volume. How easily and how much the volume changes is determined by the soil's plasticity. It is an important factor influencing ease and outcome of soil tillage operations. Soil plasticity is caused by the lubricating film of water surrounding soil particles that allow the soil to change shape without rupturing upon the application of forces. As an inherent soil property, it is governed primarily by the surface area of the soil particles. Plasticity increases with increasing clay content, activity of clay minerals, position of the adsorbed cations in the lyotropic series, and organic matter content.

DEFINITION

The adverb plastic is derived from the Latin noun *plasticus* [from Greek: plastikós (plássein)] meaning form or mold. Plasticity is the property of a solid body being molded, receiving form, or being brought into form. If the force leading to plastic deformation exceeds a yield value, permanent change in shape or size occurs. The definition of plasticity for soils includes the conditions that the deformation must not result in rupture and that the shape remains unchanged after water is removed during drying.^[1]

Although soil plasticity is closely related to soil consistence or consistency, there are two main differences: 1) Consistence and consistency usually refer to the resistance to deformation at a moisture content of the soil in the field^[2] and are a manifestation of the forces of cohesion and adhesion within the soil at various water contents.^[3] Plasticity is usually described with the soil nearly saturated with water^[4] or at water contents where the soil can easily be deformed. 2) Soil consistency or consistence is usually evaluated on undisturbed soil aggregates, fragments, or peds. Plasticity is assessed on disturbed, often wetted, and molded soil material. The latter can therefore be regarded as an inherent soil property that does not change with the soil's macro structure.

The Atterberg limits^[5] are most commonly used as parameters to describe soil plasticity, which is measured by the plasticity index (PI). PI is equal to the water content difference at the liquid limit (LL) and the plastic limit (PL). Although rarely used by the agriculturally oriented discipline of soil science, soil engineers frequently use the Casagrande Plasticity Chart^[6] to describe soil plasticity. It is a plot of the PI against the LL. Many fine-grained soils lie scattered along a line on the Casagrande Plasticity Chart:

$$PI = 0.73(LL - 20) \quad (1)$$

The units for the PI and LL are g water/100 g dry soil.

The line defined by this equation is called the Casagrande A-line. Engineering classification schemes use the position of soils on the chart in terms of their relation to the A-line for classification purposes. Soils with similar LLs tend to have greater soil toughness and dry strength when the PI increases.^[7]

The PL is generally regarded as the most suitable soil water content for seedbed preparation. Compared with wetter or drier soil water contents, it tends to give the best tilth and least cloddiness. However, the soil's compactibility tends to be the greatest at soil water contents slightly wetter than the PL.

THEORY OF SOIL PLASTICITY

Water Films

Water in soil is held inside pore spaces and is adsorbed along the surfaces of the soil particles as a thin water film. The latter determines the soil's plastic behavior because the water film acts as a lubricant between particles. The lubricating effect is most pronounced if particles are small, are platy, and are in face-to-face contact.

Cohesion

The same forces that determine the soil's behavior during the application of stress govern the dynamics of the soil's plastic behavior: cohesion, adhesion, and angle of internal friction. Soil properties that determine the response to these forces, and therefore degree of plasticity, are texture, the presence of cementation agents, cation exchange capacity and type of cations, salt concentration, soil water content, pH, and organic matter content.^[8–10]

Cohesion can be separated into true and apparent cohesion. Apparent cohesion holds particles together through capillary forces and interlocking of rough particle surfaces.^[7,11] It allows sands to be deformed without rupture, but this deformation is not plastic deformation since molded sands fall apart when dry. True cohesion holds particles together through electrostatic and electromagnetic forces of attraction and cementing agents. True cohesion is the force field for plasticity.

FACTORS AFFECTING PLASTICITY

Clay Content and Clay Type

The specific surface area of soils and thus their plasticity are largely determined by clay content. However, despite a highly significant empirical relationship between the Atterberg limits and clay content, the reliable prediction of one from the other is often not possible, unless similar soil types are considered.^[12–16]

The plasticity of different types of clay minerals is related to the size of their surface area, shape of the clay lattice, and the type of exchangeable cations. Platy or sheet-like structures are more plastic than tetrahedra-type structures. An assessment of plasticity, or any other soil property, in relation to clay mineralogy must bear in mind that natural soils usually do not contain appreciable amounts of pure primary clay minerals. Therefore, only a broad relationship can be indicated when relating clay mineralogy to plasticity.

Soils can be differentiated into the following three groups by the way in which their physical properties relate to plasticity.^[17]

1. Soils where the void volume changes little with changes in soil water content. These soils are generally governed by low activity or 1:1 clay minerals such as kaolinite, halloysite, serpentine, and berthierine. Owing to their relatively low specific surface area ($10\text{--}150\text{ m}^2\text{ g}^{-1}$) and low cation exchange capacity ($<15\text{ cmol} + \text{kg}^{-1}$), they have low values of plasticity.
2. Soils where the void space changes reversibly with changes in soil water content. These soils are typically governed by high activity or 2:1 clay minerals. The most common types of clay minerals in soils are illites, vermiculites, smectites, and chlorites. Their specific surface area is typically $50\text{--}800\text{ m}^2\text{ g}^{-1}$ and cation exchange capacity $20\text{--}200\text{ cmol} + \text{kg}^{-1}$, thus having a much greater plasticity than the low activity clay minerals.
3. The last group are soils where the void volume changes with soil water content but is largely irreversible. These soils contain appreciable amounts of allophane. Upon drying, the plasticity of these soils decreases irreversibly possibly due to the permanent collapse of a large

number of dehydrated micropores.^[18] The degree with which allophane soils change their plastic behavior upon drying can be used for classification purposes.

The impact of other clay size particles in soils [sesquioxides, manganese and silicon oxides, and calcium (Ca) and magnesium (Mg) carbonates] on soil plasticity is largely associated through their ability to cement particles together and thus tends to decrease plasticity or causes subplastic behavior.

Cations

The impact of different types of cations on the plasticity of soils is related to the size of the hydrated cation as well as to its charge, i.e., their position in the lyotropic series. Divalent cations (Ca and Mg) tend to increase both Atterberg limits and the plasticity of soils. Due to its larger effective ionic radius, Mg has a stronger effect on the Atterberg limits than Ca.^[19] Monovalent cations [potassium (K) and sodium (Na)] lower both Atterberg limits, but the K cation tends to decrease and the Na cation tends to increase plasticity.^[20]

pH

The effect of pH on plasticity is indirect and associated with the influence of pH on cation exchange capacity, amount of exchangeable bases, and soil organic matter.

Organic Carbon

Soil organic matter has a high absorptive capacity for water. Lubricating water films tend not to form unless the hydration of organic matter is fairly complete. Therefore, organic matter increases the Atterberg limits but tends to have little effect on the PI.^[1,13–16] Besides the total amount of organic matter, type or quality of organic matter influences plasticity. On soils with similar texture and organic matter content, the presence of long-chained lipids tends to shift the Atterberg limit to higher soil water contents.^[21]

TYPES OF PLASTICITY

Three different types of plasticity, based on the apparent change in clayiness when a standard field texture test is carried out, can be distinguished as follows:^[2]

1. Soil with normal plasticity only shows minimal apparent change in texture during the field texture test.
2. Subplastic soils are those where the texture appears to become finer or heavier as the soil bolus is worked for the field texture test.
3. Superplastic soils are those where clayiness diminishes as the soil is worked.

Super plasticity may be of little practical importance. Soils that could fall into this category are very sticky clays found in buried soils formed through weathering of glacial drift. Most soils have normal plasticity. Although subplastic clay soils are mainly reported in Australia, they probably occur worldwide. Soils with subplastic properties appear to be associated with very strongly bonded silt size aggregates consisting largely of fine clay.^[22] Subplasticity of Oxisols was attributed to cementation by iron oxides, while on Alfisols it was attributed to the presence of packets or domains of strongly oriented clay but not Ca carbonates.^[23] Removal of the cementation agents in subplastic clays revealed the presence of highly active (2:1) clay minerals.^[24] The degree of dispersion of subplastic clays has a strong impact not only on the outcome of texture analysis but also on the outcome of many soil chemical analyses.

Abstract

Plinthite is a material that is made up of iron oxides and forms deep in soils under certain specific conditions. Other minerals such as quartz, kaolinite, gibbsite, and birnessite may also occur in this material. Petroplinthite forms from the hardening of plinthite. Recementation of plinthites or petroplinthites forms the petroferic contact. Such features can be found in several soil types. Plinthite is distributed over large areas in India, and petroplinthite gravel is present in the peneplains. West Africa has the largest contiguous extent of soils with plinthite. The largest extent of soils with petroferic contacts also occurs in West Africa (Ivory Coast, eastern Ghana, Burkina Faso, and Central African Republic) and sporadically in the eastern part of southern Africa. Irreversible hardening upon exposure marks the advent of major water percolation problems and root penetration difficulties in soils having these features. Such soils complicate site yield predictions in plantations and also cause a drop in overall average yield for the land. Soils with plinthites can be easily mismanaged, especially in zero to low input agricultural systems. There is a lot to discover regarding the resilience of such soils.

INTRODUCTION

Plinthite is a term used to describe a soil feature that culminated from a change of physical characteristics through exposure to the atmosphere. This feature commonly occurs as reddish redox concentrations in a horizon with various kinds of patterns. This entry describes the genesis and morphology of these features as well as impact of their presence on use and management of the affected soils. Geologic deposits of ironstones and bauxite, which have other modes of formation, are not considered in this entry.

HISTORICAL PERSPECTIVE

Laterite is a highly weathered material, rich in secondary oxides of iron, aluminum (Al), or both.^[1] The material has very low amounts of basic cations and primary silicates but, conversely, may be enriched in quartz and kaolinite. Laterites are either hard or capable of hardening on exposure to wetting and drying cycles. The term laterite originated in 1807,^[2] but the first mention of it in formal scientific literature was in 1821.^[3] Geologists, engineers, and pedologists consider laterite as some kind of sesquioxide accumulation that ranges from weathered rock to hard and cemented ironstone. The term Latosol^[4] was introduced to distinguish it from laterite but was later suggested to be abandoned.^[5,6]

These older terms were replaced with modern terms such as plinthite,^[7] petroplinthite,^[8] and petroferic contact.^[7]

DEFINITIONS

The term plinthite (Fig. 1) is derived from the Greek word “plinthos” meaning brick. Other definitions for this term have been introduced.^[6,7,9] Absolute amount of iron in plinthite is site dependent. Initially, diffuse mottles separated by bleached interconnected zones form in the soil. A continuous phase of plinthite is formed eventually, through the accretion of iron with time. Plinthite usually forms deep in the soil and, therefore, has low amounts of organic matter. Erosion and truncation of the soil could expose the plinthite. Subsequent to these processes, secondary enrichment with organic matter could occur.

Plinthite normally has a sharp upper boundary to surficial layers of the soil but a diffuse lower boundary to reduced subsurface layers. The basic form of plinthite consists of quartz (silt and sand size) in a matrix of kaolinitic clay (with possibly some mica). In extreme cases, gibbsite, goethite, and hematite can also occur in addition to quartz and kaolinitic clay.^[10] Manganese (Mn) minerals such as birnessite and lithiophorite can also be present and, consequently, color the system black.

Petroplinthite (formerly known as ironstone or lateritic gravel) forms either directly in a soil or from the hardening

Fig. 1 Plinthudult from Peninsular Malaysia (plinthite is the combination of red and white mottles. The red blotches harden into hard petroplinthite when exposed and dried).

of plinthite. Petroplinthite usually occurs as loose or slightly cemented gravel.^[10,11] Recementation of plinthites or petroplinthites by rapid and cyclic influx of iron forms the petroferic contact. Alternatively, the contact can also develop on exposed ironstone gravel brought to the surface through uplift and erosion.

MODE OF FORMATION AND MORPHOLOGY

The pedological environment in the tropics is conducive for the formation of plinthite and related sesquioxide accumulations.^[6] The chemical processes resulting in the formation of these sesquioxide forms are quite complicated.^[6] A large supply of iron is needed to form plinthite. The origin of iron is normally difficult to ascertain.^[12] Downslope migration and subsequent accumulation of iron at lower levels in the landscape constitute one mode of formation.^[5] It has been suggested that iron can diffuse upwards (with fluctuating groundwater) toward oxidizing zones.^[13]

Cementation in soils may be due to two different chemical processes—1) ionic chemical bonding within the compounds (in petrogypsic and petrocalcic horizons); and 2) elements with intermediate electronegativity, such as silicon, Al, iron (Fe), and Mn,^[14] that form covalent bonds within the cementing agents and with other soil constituents.^[15] Even in crystalline forms, these compounds have outer surfaces composed of OH₂—OH groups that can be used to form covalent bonds with the same elements.^[6] This results in the high density of the cement.

Cementation and hardening of petroplinthite are attributed to the close packing of crystals.^[16] Submicroscopy studies indicate that the crust of Fe nodules is made up of densely packed Fe oxides.^[10,11,17] Iron accumulates on this rigid surface, subsequently increasing the thickness of the crust. Interior regions of the nodules usually have higher porosities as a consequence of the random orientation of minerals.^[10,11,17] It has been suggested that formation of

kaolinite is possible with Fe accretionary formations.^[18–20] Variations in ultramicroporosity and redox potentials appear to determine the type and geometry of minerals.^[17]

Alternating wet and dry conditions also favor hardening.^[6] Other factors that favor the hardening process include an ustic soil moisture regime^[7] or geomorphic changes in the landscape such as uplift or lowering of the groundwater table. Postuplift erosion eventually exposes the hardened zone (most evident at the edges of uplifted zones). The resistance to further erosion causes the formation of escarpments and inversion of the landscape.^[21] Consequently, the altered local hydrology usually favors the development of petroferic contacts in the soils.

OCCURRENCE AND DISTRIBUTION

The various forms of sesquioxide accumulations discussed earlier can be found in several soil types. The sharp upper and lower boundaries to the petroplinthite represent discontinuities in the soil. Active plinthite formation is usually found in relatively young landscapes that have fluctuating water tables in the soil. Plinthite is distributed over large areas in India, and petroplinthite gravel is present in the peneplains. West Africa has the largest contiguous extent of soils with plinthite. Such soils are present as a band from the West Coast of Gambia in the north to Cameroon in south and extend to southern Sudan and eastern Zaire.^[6] South of this band, soils with petroplinthite occur. The largest extent of soils with petroferic contacts also occurs in West Africa (Ivory Coast, eastern Ghana, Burkina Faso, and Central African Republic) and sporadically in the eastern part of southern Africa.^[22]

MANAGEMENT IMPLICATIONS

Pure Laterites and Latosols cover the greater part of the humid tropics and are either agriculturally poor or virtually useless.^[23] Essentially, the six major agro-management-related problems for such soils are irreversible hardening upon exposure, restriction to water flow, reduction in soil volume for root development, soil degradation, high remediation costs, and irreversible phosphorous fixation. The cause–effect relationships involving all these stresses, and the subsequent impact on land productivity remain unclear. Corrective measures to overcome these problems are usually not undertaken, because such projects are considered to be economically not viable. Economic and social factors have an impact on the use and management of such soils. However, these factors will not be discussed in this entry. Another effect of the presence of such soils would be the gradual reduction in carbon-sequestration capacity.

Irreversible hardening of plinthite occurs when the vegetative cover is removed.^[24] The presence of plinthite, petroplinthite, or petroferic contacts indicates that some restriction to water^[25,26] and root penetration as well as

natural soil degradation processes exists. Water flows faster above the plinthite but movement within this material is slow and restricted to the bleached zones.^[25,26] Perched water above the plinthite layer restricts the potential use of such soils to crops that require saturated conditions, such as rice. Landscape evolution and climatic change can modify the hydrology.^[27]

Quality of such soils declines (degradation) for agriculture and engineering purposes. Storage capacities for moisture and nutrients reduce with decrease in effective soil volume. Plinthite by itself poses few constraints to agricultural use of the soil.^[6] Global climatic changes (increased aridity) enhance the development of petroplinthite or petroferic contacts. The Fe nodules tend to have elevated phosphorus (P) contents and higher P sorption capacities compared to the soil fines.^[28]

In the humid tropics (e.g., Malaysia), such soils are being used for rubber and oil palm cultivation. Apart from lowering the average yield, the presence of such soils complicates site yield predictions, fertilizer recommendations, and also leaf and soil sampling for nutrient analyses. Increasing demands for food have forced these soils to be cultivated. Mismanagement of such soils has resulted in erosion rates of up to 100 ton/ha/yr. Eventual exposure of the petroferic material causes such soils to be abandoned. Soil remediation is very expensive. In addition to this, revegetation techniques are extremely time-consuming. Reforestation may be the only viable option for such soils.^[6] There have been studies that try to understand plinthite better in order to increase agricultural productivity.^[29–33]

Laterite has always been a cheap raw material for the construction of roads and walls in the tropics. However, the raw material is not considered to be very durable. Methods to enhance the performance of the material include treatment with lime, bitumen, or even cement.^[34] Stabilized soils have been used in road construction since the Roman times.^[35] Firing improves the durability of lateritic soil blocks.^[36] However, many of these methods are expensive and may not be viable options in developing nations.

CONCLUSION

The problem soils discussed in this entry are present in many developing countries in the tropics. Such soils can be easily mismanaged. Several agro-management and engineering-related problems can be identified. The average farmer cannot manage these soils at high input levels. Zero- and low-input agricultural systems on such soils enhance soil degradation. The exact areal extent of such soils in many tropical countries is unknown. There is also a lack of knowledge of the resilience of these soils to development. These issues merit rigorous and immediate attention.

Podzols

Peter Buurman

Wageningen University, Wageningen, the Netherlands

Abstract

Podzols are formed in boreal climates, on poor parent materials. Iron and aluminum are transported from upper horizons to the subsoil, predominantly as organic matter complexes. Organic matter accumulation takes place because of the root input and dissolved carbon and is regulated by its mean residence time. Agricultural use of Podzols is limited by climate, fertility, water availability, and rootability.

BACKGROUND

Podzols are mineral soils with transport and accumulation of organic matter, extractable iron (Fe) and aluminum (Al) oxyhydrates and, sometimes, amorphous aluminum silicates. The soils are common in boreal climates on all kinds of parent materials and in other climates on siliceous parent materials. Podzolization in siliceous parent materials is enhanced by hydromorphic circumstances and lateral water flow.

In the following, the typical morphology and mineralogy of Podzols are described and explained by complexation and humus dynamics.

MORPHOLOGY

Macromorphology

Podzols have a characteristic horizon sequence, consisting of O–Ah–E–Bh–Bs horizons.^[1] The O-horizon is well developed in boreal Podzols while the Ah horizon (requiring biological mixing) is more pronounced in Podzols on siliceous materials (henceforth, non-boreal Podzols). The B-horizon of boreal Podzols is generally colored more by iron compounds than by organic matter (Fig. 1). In non-boreal Podzols, organic matter accumulation in the B-horizon is more pronounced, resulting in dark brown and black colors (Fig. 2). With time, the B-horizon moves toward greater depth and the E-horizon becomes thicker. Non-boreal Podzols may show clearly distinguishable Bh1–Bh2–Bs horizons, in which case the Bh1-horizon is depleted of iron compounds and shows the maximum concentration of extractable aluminum.

Poorly drained sandy Podzols with lateral water flow frequently have pronounced parallel humus bands in the B-horizon (hardpans, Fig. 3), while the E–B transitions may fade as a result of groundwater movements. Poorly drained Podzols may be completely devoid of extractable

iron compounds. Fig. 4 depicts morphological transitions in relation to the groundwater level.

Micromorphology

Podzol profiles show various humus forms, the relative abundance of which may change with depth.^[2] In the litter layer (O-horizon), relatively undecomposed plant remains dominate and humified material appears mainly as coprolithic pellets (Fig. 5). In the E-horizon, organic matter contents are very low and remnants generally occur as very thin coatings, which are remains of former B-horizon accumulations. In well-drained B-horizons, pellet-like organic matter originating from decay of roots by mesofauna dominates. Such pellets eventually merge into aggregates and even into coating-like structures on peds or sand grains. In poorly drained Podzols, the non-rooted parts are dominated by organic matter coatings (Fig. 6). Such coatings are also found in the deeper parts of well-drained Podzols, frequently in horizontal, irregular humus bands.

MINERALOGY

Through low pH and complexation of metals by organic matter, the podzolization process causes severe weathering of minerals in Ah and E horizons. Feldspars, muscovites, biotites, apatites, pyroxenes, and amphiboles disappear eventually, while their weathering products are either transported downward (Al and Fe compounds) or degraded further (clay minerals). Muscovites and chlorites lose their interlayer material and open up, eventually exhibiting properties of vermiculites or even (Al)-smectites. The accumulation of aluminum in the B-horizon may cause local chloritization of vermiculite and smectite (soil chlorite). B-horizons may further have an accumulation of amorphous aluminum silicates (proto-imogolite) or gibbsite. The iron minerals accumulated in the B-horizon are usually goethite and ferrihydrite.

Fig. 1 Boreal Podzol on schist, Swiss Alps.

FORMATION OF PODZOLS

The major processes in Podzols are removal of Al and Fe from Ah- and E-horizons and their accumulation in the B-horizon, together with varying amounts of organic matter.

The removal of Fe and Al compounds from the upper horizons and their accumulation together with organic matter in the B-horizon have been explained in various ways. It is generally accepted that Fe and Al can be complexed by water-soluble organic matter and be transported away from Ah- and E-horizons by percolating

Fig. 2 Non-boreal Podzol on quartz sand, Belgium.

Fig. 3 Hydromorphic Podzol on quartz sands with thick Ortstein bands in the subsoil, the Netherlands.

water. There is more discordance about the process of accumulation. The classical “fulvate” theory^[3] postulates that organic molecules precipitate when all complexing groups are bound to metal ions. The fact that the carbon to sesquioxides molecular ratio of extracted organic matter and Al + Fe in the top of the B-horizon has similar values in many profiles and that this value is dependent on pH seems to point in this direction. This process, however, would mainly produce organic matter coatings, which is at variance with the fact that root-derived, pellet-like organic matter dominates in most well-drained Podzol-B-horizons. Because of their relative abundance of nutrients and better water-holding capacity, well-drained Podzol-B-horizons usually show abundant roots, and the fact that such horizons are dominated by root-derived material is not surprising. The relative abundance of coatings and pellets is related to the relative contribution of dissolved organic carbon

(DOC) and root organic matter and to organic matter dynamics.^[4]

Also, the relative dominance of sesquioxides in B-horizons of boreal Podzols and that of organic matter in B-horizons of Podzols on poor parent materials can be explained by soil organic matter dynamics.^[4] At a relatively high soil fertility, organic matter is rapidly broken down, while under nutrient-poor circumstances, breakdown is much slower. This is illustrated by high mean residence times (MRTs) of organic matter on poor parent materials, independent of climate (MRTs of 1000–4000 years) and much lower MRTs (350–750 years) in the much nutrient-richer boreal Podzols. The higher the MRT, the stronger is the accumulation of organic matter in the B-horizon. In boreal Podzols, accumulated DOC is much less than root-derived organic matter and therefore organic coatings are scarce. In non-boreal Podzols, DOC is better preserved and it dominates especially under hydromorphic circumstances when root contribution is low.

Formation and deepening of the E-horizon require removal of organic matter from the top of the B-horizon. There is no evidence of remobilization, and metal-complexed organic matter is relatively stable against microbial attack. The removal of metal ions from the top of the B-horizon by percolating unsaturated organic matter allows microbial decay of the metal-depleted humus.^[5] This results in breakdown of the upper fringe of the B-horizon and a gradual deepening of the E-horizon. This is in agreement with the predominance of relatively recalcitrant organic fractions in the E-horizon. The preservation of root-derived organic matter is similar to that of dissolved organic matter bound Al and Fe ions protect against microbial decay, and decay sets in when such metal ions are removed by percolating organic molecules.

Alternative Theories

There are some alternative theories about Podzol formation. Because Podzol-B-horizons on parent materials rich in weatherable materials may have proto-imogolite in the B-horizon, some authors postulate that Fe and Al are transported as positively charged silicate sols that, upon increase in pH, precipitate in the B-horizon as amorphous silicates.^[6] Percolating organic matter would then be adsorbed on these sols. Because organic molecules would strongly compete for metal ions with the silicate moiety, such an explanation would require a separation in time of Al/Si and organic matter accumulation. It seems more likely that percolating Si (as silicic acid) would recombine with Al to form proto-imogolite upon breakdown of the organic carrier of the Al ion. This is compatible with rapid humus dynamics (short MRT). Podzols with proto-imogolite are typically boreal Podzols with little organic matter accumulation.

Some authors emphasize the importance of low-molecular weight organic acids as carriers of complexed

Fig. 4 Podzol hydrosequence on quartz sands.

Source: From Buurman.^[1]

metals. The metals would precipitate upon microbial breakdown of the carrier. This is probably a major mechanism in boreal Podzols and an important one in others. In non-boreal Podzols, it seems that upon breakdown of the carrier, complexed metals are transferred to organic moieties of larger molecular weight and higher recalcitrance.^[7]

ORGANIC MATTER CHEMISTRY

Pyrolysis-gas chromatography-mass spectrometry indicates that Podzol A horizons closely reflect the litter input and have abundant lignin-derived compounds. E-horizons are dominated by recalcitrant aliphatic moieties, and the composition of B-horizons depends on

Fig. 5 Pellet-like organic matter in a well-drained Podzol-B-horizon, the Netherlands.

Fig. 6 Thick, fragmented organic coatings in a Podzol on quartz sands from New Zealand.

the relative abundance of root-derived and DOC-derived organics. Root-dominated B-horizons have high polysaccharide contents, while phenols and other small aromatic molecules dominate DOC-derived organic matter.^[5]

OCCURRENCE OF PODZOLS

and in pine and birch forests. This is caused by the slow decay of litter and consequent continuous production of complexing and water-soluble organic acids that weather topsoil minerals and transport Al and Fe in a complexed form. Toward milder climates, Podzols give way to other soils because the breakdown of complexing organic matter is too rapid and because biological mixing is more intense (obliterating any differentiation that might be caused by eluviation). In drier cold climates, there is insufficient production of litter and organic acids, along with lower percolation. Boreal climates are found both at relatively high latitudes and at high altitudes, and mountain Podzols have essentially the same properties as the Podzols of high latitudes.

Podzolization on nutrient-poor parent materials such as quartz sands is found in virtually all climate zones with sufficient rainfall. They are well documented from places like Central Europe, the Northern United States (Lake Michigan dunes), the Pigmy forest of California, the Amazon basin, uplifted beaches in Malaysia and Borneo, dune sands of Central Africa, and sandstone debris in eastern Australia. Such Podzols frequently are formed under the influence of both a poor parent material and an impeded drainage combined with a lateral groundwater flow. Sometimes, Podzols develop on Oxisols as a result of impeded drainage and clay destruction by ferrollysis, or on siliceous volcanic ash (ignimbrites). The extent of Podzols by continent is given in Table 1.

AGRICULTURAL USE

Podzols impose various restrictions to agricultural use. In boreal Podzols, climate is the main restriction. In non-boreal Podzols, both the low fertility and the stratified structure impose restrictions on the plant growth. Well-drained Podzols can be deep plowed to erase the layered structure and increase the water availability of the plowed zone. Poorly drained hardpan Podzols need both improved drainage and deep plowing to increase rootability. All Podzols tend to be poor in nutrients, especially nitrogen and phosphate. Poorly drained Podzols frequently lack trace elements, as they are removed from the profile through lateral water flow. In general, Podzols will produce adequately only under good management.

Land and Soil Consultancy Services, Nelson, New Zealand

Abstract

Soils of the polar regions cover approximately $20 \times 10^6 \text{ km}^2$. They occur in the coldest parts of the globe; therefore, their development is dominated by cryogenic processes, resulting in unique soil properties. These soils sequester organic carbon and store this carbon in the subsoil for thousands of years. Most of this carbon is in a frozen state and could be released into the atmosphere as greenhouse gases due to climate warming. These released greenhouse gases could then further accelerate the global warming.

INTRODUCTION

The polar regions encompass all land and water areas surrounding the north and south poles and include all of the global permafrost regions. The northern treeless part of this region is commonly known as the Arctic in the northern hemisphere and as Antarctica in the southern hemisphere. Since these regions have the earth's coldest climates, most of their soil materials are perennially frozen, and their development is dependent on the amount of moisture in the soil and the stability of the landscape.

Knowledge of the polar soils has advanced greatly since the 2000s, especially for the Northern Circumpolar Soils (NCPS). The development of seamless soils and soil carbon databases are able to demonstrate the huge amounts of soil carbon stored in these soils. Using these databases, several types of soil maps were produced (Fig. 1). Because of the global significance of this soil carbon, accelerated research was carried out by various disciplines on the characteristics, decomposability, and fate of this soil carbon due to climate change. Most of these activities were associated with significant amounts of field work in spite of the remoteness and inaccessibility of this region. To make the polar soils more available for a wide range of people, the Soil Atlas of the northern circumpolar region (NCPR) was published and made available for the government departments, libraries, and the general public.

ENVIRONMENTAL SETTING

The NCPS covers approximately $19 \times 10^6 \text{ km}^2$, and about 54% of this soil area is associated with perennially frozen soils. Most of the perennially frozen soils in the northern hemisphere occur in Canada and Russia. Glaciers cover approximately $1.9 \times 10^6 \text{ km}^2$ of this area, with most glaciers (92% or $1.7 \times 10^6 \text{ km}^2$) occurring in Greenland.

Although Antarctica is large (approximately $14 \times 10^6 \text{ km}^2$), 99.7% of it is covered by ice caps. The ice-free portion ($0.05 \times 10^6 \text{ km}^2$) that includes soils is found in many widely scattered small areas, the largest being the McMurdo Dry Valley region.

Short, cold summers and long, extremely cold winters characterize the climates of both polar regions. Mean daily temperatures above 0°C occur only during the warmest part of the summer. Total annual precipitation is generally low and occurs mostly as snow. In Antarctica, the annual precipitation averages 50 mm, ranging from less than 10 mm in some parts of the Transantarctic Mountains to greater than 100 mm in northern coastal regions. Effective precipitation is low, however, since most snowfalls either blow away or sublime. Vapor exchange is important in soil moisture transfers. However, soil moistening from snow thaw persists for only a few days.

The common vegetation associated with the NCPS is a conifer forest in the southern part of this region, and north of the tree line is a shrub-tundra grading into a sparse vegetation cover moving northward. Most of the Antarctic soils are unvegetated. Permafrost is continuous in both the Arctic and Antarctic, and the terrain is associated with patterned ground. Based on the Northern Circumpolar Soil Carbon Database,^[1] Turbels^[2] are the dominant soils covering approximately $6.5 \times 10^6 \text{ km}^2$. The second most common soils are the Histels^[2] ($2.7 \times 10^6 \text{ km}^2$) and followed by the Orthels^[2] ($1.1 \times 10^6 \text{ km}^2$). Seasonally frozen soils occur commonly in the southern part of the NCPR, and these are the Inceptisols, Spodosols, Histosols, Entisols, and Molisols.^[2]

SOIL-FORMING PROCESSES

Soil formation in the NCPR is dominated by cryogenic processes, which are driven by the presence and mobility

Fig. 1 Map showing the distribution of permafrost-affected soils (Turbels, Orthels, and Histels) and seasonally frozen soils in the northern circumpolar area. The various permafrost zones and the location of the arctic tree line are also shown in this map. **Source:** From Tarnocai, Canadell, et al.^[1]

of unfrozen soil water as it migrates toward the frozen front, along the thermal gradient in the frozen system. These processes, which produce a dynamic landscape, include freeze-thaw, cryoturbation or frost churning (Fig. 2), frost heave, cryogenic sorting, thermal cracking, patterned ground, and ice segregation. Other soil-forming processes that can leave an imprint on these soils include the gleying process, brunification, eluviation, and salinization.

In the Antarctic or southern circumpolar region, however, soil formation is dominated by weathering processes because of the extraordinary landscape stability resulting from the exceedingly cold and arid climate. Patterned ground develops widely in these dry Antarctic soils, especially on younger land surfaces, but the presence of volcanic ash in the cracks indicates that cryoturbic mixing is limited. Since almost all precipitation occurs as snow, which blows away or sublimates, little moisture is transferred

Fig. 2 Strongly cryoturbated permafrost-affected soil from Arctic Canada. Cryoturbation is displayed by the strongly contorted mineral and organic horizons.

Fig. 3 A Miocene-age soil weathering profile on till from near the head of Hatherton Glacier, Antarctica. There is a well-developed surface pavement and a salt horizon at 15 cm. The soil is dry-frozen with the active layer depth at approximately 10 cm. Soil colors are reddish brown (5YR 4/4) at the surface passing to light yellowish brown (10YR 6/4) at depth.

to the soil; therefore, cryoturbation and ice buildup are minimal or non-existent. As a result, cryogenic processes have little or no effect, and weathering processes, which operate over long periods on this stable landscape, dominate, even though they act extremely slowly. The soils thus produced are brunified (Fig. 3) and often contain salt accumulations.

Weathering processes operate extremely slowly in the Arctic as well as in the Antarctic. Physical weathering takes place mostly at the surface. In the Antarctic, clast reduction occurs through abrasion, exfoliation, granular disintegration (salt weathering), and thermal fracture. Frost weathering (frost shattering) is minimal in the Antarctic because of the absence of water, but it is more active in the Arctic, where the soil moisture content is higher. The dominant chemical weathering processes in Antarctic soils are oxidation and salinization.^[3,4] Because evaporation exceeds precipitation, salts accumulate in the Antarctic soils in a variety of forms, commonly in distinct horizons. Although salt composition of the soil partially reflects that of the soil parent material, it typically mirrors atmospheric and climatic gradients, indicating that aerosolic transport is the main source. Clay mineral formation is limited in both Arctic and Antarctic soils.

Fig. 4 Lowland ice-wedge polygon landscape, Mackenzie River Delta area, Canada. The ice wedges are located in the polygonal trenches.

SOIL CHARACTERISTICS

NCPS

Cryoturbation, which is very common in this region, results in irregular or broken soil horizons, involutions, organic intrusions (Fig. 1), organic matter buildup in the subsoil (often with concentration of this material along the top of the permafrost table), oriented rock fragments, silt-enriched layers, and silt caps.^[5] Permafrost-affected soils contain various amounts of ice in the form of ice crystals, vein ice, ice wedges, and massive ground ice several meters thick (Figs. 4 and 5).

The NCPS generally has high moisture content, especially near the permafrost table, so gleying associated grayish colors and redoximorphic features develops on most landforms, including those on better drained positions. These soils are very often saturated because the active layer (the upper layer of the soil that freezes and thaws

Fig. 5 Cross section of an ice-wedge polygon area associated with Cryosols. The ice wedge is approximately 3 m wide; Mackenzie River Delta area, Canada.

annually) is shallow. Thin, eluvial, or leached horizons are common in soils in the southern part of the discontinuous permafrost zone but very seldom occur in the northern regions. The brunification associated with coarse-textured soils is usually associated with this eluvial horizon.

The active layer not only supports biological activity but also protects the underlying permafrost. The thickness of this layer is controlled by soil texture and moisture, thickness of the surface organic layer, vegetation cover, aspect, and latitude. In perennially frozen soils, the active layer normally extends from 25 to 120 cm below the soil surface.^[6,7]

Particle size distribution in perennially frozen soil, ranges from silty clay to coarse, gravelly sand. The composition of the fine earth fraction is commonly dependent on the mode of deposition of the parent materials. The pH in these soils varies greatly and also depends on the chemistry of the parent materials. The similarity of pH to that of the parent material is caused, in part, by cryoturbation, which not only mixes parent material with soil materials but also mixes soil material among the horizons.

The nitrogen, potassium, and phosphorus contents of perennially frozen soils are generally low since most of these nutrients are locked into compounds contained in the surface organic layer.^[8] Salt crusts, which form by translocation of salts from the subsurface horizons, develop during dry periods in the summer because of increased evaporation from the soil surface. Such salt crusts are common on the surfaces of high Arctic soils. Calcareous crusts on the underside of rocks are also a common phenomenon, especially in coarse-textured soils. Soils developed on fine-textured marine sediments usually have both high conductivity and high salt content.

Soils in the NCPR contain the single largest component of the terrestrial carbon pool. An estimate made by Tarnocai et al.^[1] shows that organic soils (Histosols and Histels) and perennially frozen cryoturbated mineral soils (Turbels) have the highest organic carbon contents (32.2–69.6 kg m⁻³). Organic carbon pools estimated by the same authors also show that the perennially frozen soils in the NCPR contain approximately 191.3 Pg for 0–30 cm depth, 495.80 Pg for 0–100 cm depth, and 1024.00 Pg for 0–300 cm depth. Carbon pools in depths greater than 300 cm were estimated to be 407 Pg for yedoma deposits and 241 Pg for deltaic deposits. Therefore, based on these estimates, the soils in the NCPR contain 1672 Pg of organic carbon with approximately 88% occurring in permafrost-affected soils and deposits. This 1672 Pg of NCPR carbon accounts for approximately 50% of the total belowground global organic soil carbon. This total is greater than the amount of carbon stored in the atmosphere, forests, or biosphere. Only the oceans store a greater amount of carbon than do these soils, and the oceanic carbon is much more difficult to release into the atmosphere.

The diversity of microorganisms in NCPS is much greater than that in the SCPS soils because of the higher concentrations of available water and organic matter in NCPS. These microorganisms play an important role in the

decomposition of the organic matter and in nutrient recycling.^[9]

Southern Circumpolar Soils

Although conditions for soil formation in the Antarctic are minimal, considerable spatial soil variation results from differences in soil-forming factors. The main physical features of Antarctic soils are the following:

1. A distinctive surface pebble or boulder pavement;
2. Differing characteristics associated with differing rock types;
3. A soil form dominated by coarse, but highly variable, sandy to bouldery textures;
4. Only a small increase in fine particle size, associated with increasing age;
5. Almost a complete lack of cohesion or structural development;
6. Increased reddening and increased oxidation depth with increasing soil age;
7. Increased accumulation of soluble salts with increasing soil age;
8. An active layer from < 5 cm to > 70 cm, depending on climate; and
9. Permafrost that is commonly hard and ice-cemented in coastal situations and on younger land surfaces, but dry-frozen in areas of high aridity.

In the Transantarctic Mountains, the soils may thaw for only 2 months, while moisture contents of < 1–5% are common.^[10] Distinctions based on soil temperature and moisture differences are evident. In the Antarctic Peninsula and some northern coastal regions, the soils are moister and may have organic accumulations associated with sporadic moss or grass occurrences in damp sites.

Biologically, Antarctic soils typically lack organic accumulations. Life forms are restricted to more favorable moist environments where small patches of mosses, lichens, and algae may be present. Bacteria and algae occur within the soils, supporting grazers such as nematodes, tardigrades, and rotifers.^[11]

CONCLUSION

Soils of the circumpolar regions are the coldest soils on earth. These soils have been studied since the mid-1900s, but these studies greatly accelerated since the 2000s. There is now considerable knowledge of the processes that led to the formation of these soils, and of their role in relation to the unique ecosystems of these polar regions. However, their global significance was recognized by the role they play in global climate and due to the huge amounts of organic carbon they sequester annually, and they store this carbon for thousands of years due to their unique processes and properties.

Pollution

Zulkuf Kaya

Department of Soil Science, University of Cukurova, Adana, Turkey

Abstract

Excess growth of population and urbanization on global scale along with industrialization induce pollution of soils which seriously threatens human health and ecosystem by causing irreversible hazardous effects. Thus, reaction of pollutants (decomposition, accumulation, and mobility properties) should be monitored for mitigation or if possible preventing perilous effects on living organisms. Since pollutants and heavy metals such as persistent chlorinated organic compounds (xenobiotica) and mercury could cause mutagenous and teratogenous side effects, great care and effort should be paid to prevent the transportation of the said substances to soil for sustaining biodiversity. Hence, via the sustainable ecosystem/agroecosystem concept, the status of the pollutants in soil should be monitored permanently.

INTRODUCTION

Soil—the medium of life and foundation of human existence, the contact of lithosphere, atmosphere, and biosphere—has been dominated by numerous physical (temperature and pressure changes, wind and water movements, etc.), chemical (oxidation, plant root, microorganism, excretions, solution, and neosynthesis), and biological (humus formation) processes in the past and the present, ranging from hundreds to millions of years. Ensurance of sustainable life, i.e., bound to the preservation of the natural courses of the processes as mentioned, is ultimately secured by the “quality of soil” in physical, chemical, and biological terms.

SOIL POLLUTION: THE HUMAN IMPACT

The impact of urbanization and industrialization has been a major factor against the need of preserving the quality of soil, by reducing it via chemical contaminants, use of polluted waters for irrigation, and deposition of harmful particulates to the atmosphere. Ecosystems are threatened by such contaminants and their interactions in the environment. Harmful chemicals can be studied via concepts of ecosystem/agroecosystem planning developed, keeping in mind the sources of chemical contamination, which are responsible for the degradation of environment. These sources are as follows: 1) the wastewaters; 2) the agricultural wastes; 3) the airborne pollutants; 4) the pesticides; 5) the urban wastes: a) sewage sludge, b) composts, and c) fly ash; and 6) the industrial wastes: a) pesticides and fungicides, b) fertilizers, c) detergents, and d) chlorinated solvents.^[1]

These sources may cause fatal effects and/or irreversible destructions for human health and the environment. The levels of contamination together with their ability and

mobility in decomposition and accumulation of the chemicals in the soil have been scientifically proven to be harmful to animals, plants, and microorganisms via destroying the natural structure of water, soil, and air, which is balanced by nature.^[2]

Inactivated enzymes are the measure of heavy metal (divalent) toxicity readily reacting with proteins, amines, and sulfohydryl (–SH) groups as well as mercury (Hg) and cadmium (Cd) replacing zinc (Zn) in metallic enzymes. Metal toxicity is known to decrease cell membrane permeabilities and change genetic characteristics of cells increasing risks of cancer. Hg accumulates in fatty tissues as methyl-Hg, whereas Cd replaces calcium in bones and kidneys destroying their excretory functions.

According to Förstner,^[2] the behavior of synthetic organic compounds in soils are not “sorptive” processes but are related to dissolution mechanisms on lipid-like particle surfaces ousted from soil solutions. Functional groups varying in molecular size, form, and valency such as the cationic, basic, and acidic solutions together with non-polar compounds are also responsible for the “sorption” of organic chemicals by solids.

Ecological studies have been carried out on the decomposition or hydrolysis of chemical bonds from water-soluble pesticides such as methylcarbamates or organophosphoric insecticides revealing shorter duration periods in soils than organochlorine compounds. However, weak bonding compounds of the chlorophenol group are easily mobilized by pH changes and other unknown environmental impacts and expose higher risks for human and environmental health.

The highly persistent and biologically unsynthesizable “xenobiotica,” i.e., the organic compounds with the highest poisoning risk such as 2,3,7,8-tetrachlorodibenzodioxine with a lethal dose of 1 µg/kg body weight are 1000-fold more poisonous than sodium cyanide.^[2]

Table 1 Contents of source materials causing pollution in cultivated soils (mg/kg).

Elements	Fertilizers ^a	Sewage sludge	Domestic compost	Fly ash	Precipitation ^b
Cd	P(50)	12	10	10	0.25
Cr	P(200)	250	120	280	1.4
Hg	Trace	4.4	—	—	0.05
Ni	Trace	80	120	270	7.3
Pb	P(100)	700	1200	330	11.0
Zn	P(150)	3000	2000	360	29

^bThe estimated accumulation in surface soils (top 20 cm) in 100 years by atmospheric precipitation.

Source: Adapted from Berrow.^[3]

Metals such as lead, arsenic, Hg, chromium, Cd, and copper are found at acceptable limits in nature. However, these limits might increase with contamination from agricultural, industrial, and infrastructural wastes (Table 1). For instance, concentrations of lead might increase by the gaseous emissions of vehicles and use of garbage compost as a fertilizer together with pesticides. Arsenic is naturally found at a level of 10 ppm in soils and might also increase to 500 ppm with industrial wastes and agricultural applications. Lead arsenate applications in orchards are determined to increase lead to 121 ppm.^[1] Hg, which is determined to be between 90 and 250 g/ha in normal soils, might increase at a rate of 5 g/ha/yr with the use of chemicals for cereal seeds. Additionally, about the same amount of Hg is added to the soil by rain and irrigation waters as well as garbage compost (Table 1).^[1] The increase of Cd contents in the soils of Japan has been the main reason in establishing a law for the control of soil contaminants. The behavior as well as the qualitative and quantitative distributions and conversion mechanisms of

the foreign organic materials in soils have always been obscure (Fig. 1). Fig. 1 illustrates that the independent enzymes are responsible for the biotic conversions of organic chemicals occurring together with the non-biotic. Soil quality on the long run is extensively affected by such conversions, forming non-extractable-bonded residues,^[3] even by suitable agricultural practices.^[1]

A specific extraction method for each non-extractable residue should be determined for residues absorbed within clay mineral stacks and bonded by non-covalent bonding in macromolecular spaces of humic substances, hydrogen bridges, van der Waals forces, and attractions occurring via charge transfers as well as covalent bonding to monomeric humic substances and macromolecular structure of phenols and aromatic amines.

Chemical residues bonded by humic substances in soils should be carefully controlled owing to their limited availability to plants, and lack of mineralization preventing their inclusion to the C-cycle,^[1] thus algae, fungi and lichens, protozoa, and simple metazoa are used to isolate the

Fig. 1 Behavior of pesticides in soils.

Source: Adapted from Korte.^[1]

anthropogenic chemicals from soils and soil solutions. However, information obtained on the conversion of environmental chemicals in laboratory conditions is not usually valid for field conditions, which are highly complex with different densities of populations, nutrient statuses, and conversion activities.^[4]

Microorganisms, insects, and larvae have yielded estimable results^[5] at numerous experiments conducted in field or laboratory conditions on the conversion and transportation of chemicals in soils. In spite of being tedious to handle, lysimeters with soil columns have also been documented to yield realistic results.

Cd, Pb, AND Cr CONTAMINATION IN SOILS

The natural Cd content of soils at the upper 20 cm depth is <0.5 mg/kg. Cd contents of soils in the European Union have significantly increased to 0.16–0.32 mg/kg Cd in the last decades by excess input.^[1] The sources of increasing Cd are the polluted (~1.5–35 g/ha/yr) sewage sludges (~1 g/ha/yr), phosphate fertilizers (~5–6 g/ha/yr), and others (~1 g/ha/yr).^[1]

The major source of Cd contamination in agricultural soils is the excess use of fertilizers with varying amounts of Cd contents (0.1–90 mg/kg) depending on the phosphate rock materials utilized in production. Such contaminations in soils will cause a 0.1 mg/kg increase of Cd in 20–30 years. Other spots of high Cd contamination are adjacent to Zn mines. Another significant Cd contamination source is the sewage sludge used in cultivated soils. The Cd content in the dry matter of the sludge is 7–17 mg/kg.^[1] Cd adsorption by organic or inorganic soil compounds (minerals) depends on the soil texture, pH, and Ca together with other elements. The retention of low amounts of Cd in soil solutions in surface soils might take tens or hundreds of years depending on texture.^[6] The carryover of Cd to plants does not only depend on the type and growth period but also on the availability of Cd in soils. Exchange, adsorption, fixation, and diffusion are the dominant mechanisms in soils controlling Cd uptake/carryover by plants.

Lead is less toxic than Cd in soils with contents of about 15 mg/kg in the earth's crust. This amount increases to 700 mg/kg in soils close to highway traffic. Lead is very immobile in soils compared to Cd and Zn, being slightly soluble in pH <5, whereas it is more soluble and available to plants at pH = 4–4.5.^[7]

Soil Pb contents generally vary from 1 to 20 mg/kg,^[2,6] with Pb solubility decreasing at pH > 6 and increasing in pH < 6 with increasing availability to plants. The decrease of solubility/availability has been shown in many cases and especially in Pb-free grains of corn grown in soils with high Pb (320 kg/day).^[8] Tolerable limits of Pb in soils are given by Hock and Elstner^[8] as 100 mg/kg and 50–300 mg/kg for EU standards by Förstner.^[2]

Chromium, the essential element for human and animal diets, is not considered essential for plant nutrition with a tolerable level of 100 mg/kg in soils.^[1,8] Cr³⁺ is irrevocable in its role in the induction of the effect of insulin and proteins as well as stabilizing nucleic acid structures and activating some enzymes in glucose metabolism.^[9]

Varying parent materials seem to be responsible for the wide range of chromium contents of soils (5–3000 mg/kg). High pH conditions favor the formation of new insoluble compounds—Cr(OH)₃ and Cr₂O₃ · xH₂O—with iron oxides. In strong acidic conditions, Cr is readily soluble, with a low uptake (carryover) by plants, whereas it is readily available even at very low amounts if retained by roots.^[7]

NICKEL CONTAMINATIONS IN SOILS

Soils contain as low as 5–50 mg/kg Ni,^[7] which may increase to 5000 mg/kg in soils developed from olivine and serpentine rocks. Ni reaches the soil from air, via burning coal (10–50 mg/kg Ni) and derivatives of petroleum (49–145 mg/kg Ni) transformed to Nickel carbonyl, which is cancerogenous.^[9] Sewage sludge containing high amounts of Ni is also responsible for the pollution of the soil. Clay minerals, magnesium, iron, and aluminum oxides adsorb and/or bind immobilize soil Ni depending on pH.^[10] At pH < 5.5, the solubility and plant availability of Ni increases. In soils with pH > 6—the threshold reaction for Ni—the extractable Ni content by ethylenediaminetetraacetate is 25 mg/kg. At pH < 6, lower values of Ni concentrations are needed to avoid toxicity.

Hg CONTAMINATION

Hg compounds (especially CH₃–Hg⁺) are highly poisonous for humans and animals. Excess Hg affects the central nervous system, develops blindness, and causes mutagenous and teratogenous effects via CH₃ · HgCl. The Hg content of the earth's crust is approximately 0.02 mg/kg, whereas slightly contaminated soils and sediments together with soils developed from Hg-rich parent materials (located near volcanic areas) may contain 0.5 mg/kg Hg (dominantly <0.1 mg/kg) and 40 mg/kg Hg, respectively.^[8]

Soils of highly populated areas and ore production sites contain 0.1–0.4 and 1.8 mg/kg Hg, respectively. Similarly soils, irrigated by wastewaters, contain up to 1.6 mg/kg of Hg.^[7]

The following reaction, together with microorganisms taking part in the process, shows the conversion of Hg in soils as

The low solubility of Hg in soils and its immobilization caused by the effective groups (–S–H and –S–S) in soil organic matter, by inducing accumulation in the root zone, consequently reduce the carryover to the plants.^[11]

Vegetables like lettuce and beans also seem to be suitable for growing in Hg-contaminated soils (7 mg/kg Hg) owing to their low uptake rates (0.08–0.12 mg/kg Hg), in contrast to grass containing surprisingly high amounts of Hg at golf courses with 130 mg/kg Hg.

CONCLUSION

Excess growth of population and urbanization on global scale along with industrialization induce pollution of soils which seriously threatens human health and ecosystem by causing irreversible hazardous effects. Thus, reaction of pollutants (decomposition, accumulation, and mobility properties) should be monitored for mitigation or if possible preventing perilous effects on living organisms. Since pollutants and heavy metals such as persistent chlorinated organic compounds (xenobiotica) and Hg could cause mutagenous and teratogenous side effects, great care and effort should be paid to prevent the transportation of the said substances to soil for sustaining biodiversity. Hence, via the sustainable ecosystem/agroecosystem concept, the status of the pollutants in soil should be monitored permanently.

Abstract

Pollution by industrial waste is widespread throughout the world, adversely affecting soil and environment qualities. Management of these wastes is necessary to achieve a more sustainable system. After exhausting the two approaches of preventing waste generation and recycling suitable materials, the use of wastes, by-products, or mixtures of different materials for amelioration, remediation, or recultivation is one option to regulate material fluxes.

INTRODUCTION

Anthropogenic activities such as mining and smelting, combustion of waste and fossil fuels, as well as the use of various organic and inorganic chemicals and radionuclides in agriculture and industry entail risks for the overall environment and human beings. The awareness of these risks due to industrial wastes emerged through numerous cases of severe environmental impact many years after their disposal. Notorious examples include hazardous waste disposal in the Love Canal, New York, U.S.A.,^[1] Lekkerkerk near Rotterdam, the Netherlands,^[2] or the collapsed tailing dam containing acidic pyrite sludge in Donana, Spain.^[3]

Besides the negative effects of industrial waste, their reuse potential for soil amelioration, remediation, and recultivation should also be considered. Future perspectives and visions for handling industrial waste must be discussed in terms of the potential environmental risks and how to minimize them.

POTENTIAL POLLUTION BY INDUSTRIAL WASTE

Generally, industrial activities generate the following three categories of waste: 1) gaseous emissions; 2) wastewater; and 3) solid waste. Gaseous pollutants or particulates are generated by combusting fossil fuels and wastes; they are found both close to the emittent and far away, especially in forest ecosystems due to their filter capacity.^[4] Dispersion

and long-term transport of heavy metals, radionuclides, and persistent organic pollutants occur.^[5] Acidification and eutrophication are due to the transboundary distribution of nutrients involved in combustion processes (e.g., sulfur and nitrogen compounds). Wastewater is derived from domestic and industrial establishments; in both the cases, they are known as municipal wastewater. Surface and groundwater are the most threatened sinks of pollutants, besides irrigated areas. Upon removal of water, wastewater turns to sludge and further to solid waste. Generally, solid waste generation starts with mining and petroleum production and with the subsequent processing of these raw materials to goods for consumption. Emerging waste includes mineral ores, tailings, slags, oil-contaminated soils, and residues that stem from the processing of these materials.

Industrial activities generate mostly mixed wastes, yielding transient waste types. Pollutants can be released in gaseous, particulate, aqueous, or solid form, depending on the industrial processes involved. They emanate from point or diffuse sources [see the entries *Pollution: Point Source* (p. 1776) and *Pollution: Non-Point Source* (p. 1765) for more information]. Generally, pollution tends to be highest close to emittents and declines with increasing distance. However, the elevated concentrations of persistent organic chemicals have been found in environments far from pollution sources, such as in the Arctic, in mountain regions, and in forest soils.^[6]

Soil quality is prone to degradation through 1) physical; 2) chemical; and 3) biological processes, resulting in soil

erosion, reduced productivity, and soil and groundwater contamination. Detrimental effects of industrial waste on soil comprise 1) siltation and compaction through the application of fine-grained and salt-rich materials; 2) any type of pollution, acidification, or landfilling; and 3) loss of macro- and microfaunal diversity by intoxication. Heavy metals (lead, mercury, and cadmium), metalloids (arsenic and antimony), and organic compounds (e.g., dioxins and other persistent organic pollutants) are the most relevant soil pollutants. Waste generation has dramatically increased from chemical manufacturing, wastewater treatment, agriculture, mining and smelting, food processing, energy production, pulp and paper production, and other industries. The subsequent waste–environmental interactions have potential consequences on soil and water qualities. Estimates show that up to 75% of the materials used in industrial processes do not end up in final products.^[7]

The prevention of industrial waste production, enhanced by the optimization of processes reducing the amount of generated waste and the concentration of pollutants in waste streams, has a higher priority than end-of-pipe technologies such as soil remediation.

POTENTIAL USE OF INDUSTRIAL WASTE

Soil Amelioration

In the case of metals, humankind has imbalanced biogeochemical cycles through the use of metals. Considerable amounts are lost in technical processes into the abovementioned waste categories. Electronic waste is one of the most rapidly growing problems. Waste volume estimation for 1998 is given in Table 1. Instead of exporting this waste from “developed” to “developing” countries and thereby contaminating soil and water due to the lack of legal regulations, the strategy should be to promote recycling and reuse of metals. Besides heavy metal-contaminated arable land, nutrient deficient areas are widespread over the world. Here, the reuse of copper, manganese (Mn), molybdenum,

Fig. 1 A schematic overview of waste reuse possibilities.

iron (Fe), and zinc from electronic waste as nutrients could contribute toward more sustainable systems.

Gravel sludge, a fine-grained by-product of the gravel industry—applied on sandy soils poor in nutrients—can improve soil physical properties and crop production.

On the other hand, the use of industrial waste materials as soil amendments has been estimated to contaminate thousands of hectares of productive agricultural land in countries throughout the world. This is a particular problem in the Asian Pacific region, where land-based disposal of untreated wastes is being practiced due to lack of regulatory guidelines.^[12] If crops are cultivated on contaminated soils, they may become less competitive on the world market, provided efficient quality control is implemented. Fig. 1 shows a schematic overview of waste reuse possibilities.

Table 1 Industrial waste quantities.

Industry	Industrial waste	Produced amount (Mg ^a)
Electronic industry	Electronic waste	5–7 Mio worldwide ^[8]
Alumina industry	Red mud	60 Mio worldwide ^[9]
Pulp and paper industry	Paper mill sludge	9 Mio in the United States ^[10]
Iron and steel industry	Slags	300 Mio ^a worldwide ^[11]
Energy production	Gypsum	7 Mio in Europe ^[11]
Energy production	Fly ash	37 Mio in Europe ^[11]

^aCalculated from the produced amount of iron and steel.

Soil Remediation

In situ fixation of labile metals in soils by the addition of amendments is one option to remediate heavy metal-contaminated soils. The aim is to reduce the risk of contamination by balancing ecological and economical needs. Several industrial wastes or by-products have been screened for their ability to immobilize heavy metals. Red mud is produced by the alumina industry around the world in countries like Jamaica, Australia, the United States, and Germany (Table 1). Results of greenhouse and outdoor experiments indicate immobilization of many heavy metals in soil by red mud.^[13] Similar results were obtained for

steel shots, a waste product of the metal shaping industry, Thomas phosphate basic slag from the steel industry, and "Iron Rich," generated by the titanium dioxide production. Fly ash, a coal combustion residue, and beringite, a modified aluminosilicate that originates from the fluidized bed burning of coal refuse from a former coal mine in Beringen (Belgium), also have potential for metal immobilization.^[14] The composition of these amendments varies considerably, and the immobilizing effect is mostly due to aluminum-, Fe-, Mn-oxides, phosphates, silicates, and alkaline materials.

The application rates of these amendments up to 5% (w/w) are practicable and result in establishing a vegetation cover on bare land, the reduction of visual symptoms of metal phytotoxicity, and a significant reduction of the metal accumulation in aboveground biomass.^[15]

Besides the advantages of these materials, disadvantages or failures may also occur due to indigenous contamination of the materials.^[13] The recommendation is to adjust the amendment and application rate on a case-by-case basis. In certain cases, removal of contaminants may be required.

CONCLUSION

Pollution by industrial waste is widespread throughout the world, adversely affecting soil and environment qualities. Management of these wastes is necessary to achieve a more sustainable system. After exhausting the two approaches of preventing waste generation and recycling suitable materials, the use of wastes, by-products, or mixtures of different materials for amelioration, remediation, or recultivation is one option to regulate material fluxes. Besides considering the advantages of using waste materials, the disadvantages have to be taken into account and must be assessed on a case-by-case basis.

Abstract

Environmental contaminants can have a deleterious effect on non-target organisms and their beneficial activities. The sampling requirements of non-point source pollution (NPSP) are quite different from those of the point source contamination. This entry reviews some strategies for evaluating and combatting the effects of NPSP.

INTRODUCTION

Non-point source pollution (NPSP) has no obvious single point source discharge and is of diffuse nature (Table 1). An example of NPSP includes aerial transport and deposition of contaminants such as sulfur dioxide from industrial emissions leading to acidification of soil and water bodies. Rain water in urban areas could also be a source of NPSP as it may concentrate organic and inorganic contaminants. Examples of such contaminants include polycyclic aromatic hydrocarbons, pesticides, and polychlorinated biphenyls that could be present in urban air due to road traffic, domestic heating, industrial emissions, and agricultural treatments.^[1–3] Other examples of NPSP include fertilizer [especially cadmium (Cd), nitrogen (N), and phosphorus (P)] and pesticide applications to improve crop yield. Use of industrial waste materials as soil amendments have been estimated to contaminate thousands of hectares of productive agricultural land in countries throughout the world.

CONTAMINANT INTERACTIONS

Non-point pollution is generally associated with low-level contamination spread at broad acre level. Under these circumstances, the major reaction controlling contaminant interactions is sorption–desorption processes, plant uptake, surface runoff, and leaching. However, certain contaminants, in particular organic compounds are also subjected

to volatilization, chemical, and biological degradation. Sorption–desorption and degradation (both biotic and abiotic) are the two most important processes controlling organic contaminant behavior in soils. These processes are influenced by both soil and solution properties of the environment. Such interactions also determine the bioavailability and/or transport of contaminants in soils. Where the contaminants are bioavailable, risk to surface- and ground-water and soil, crop, and human health is enhanced.

IMPLICATIONS TO SOIL AND ENVIRONMENTAL QUALITY

Environmental contaminants can have a deleterious effect on non-target organisms and their beneficial activities. These effects could include a decline in primary production, decreased rate of organic matter break down, and nutrient cycling as well as mineralization of harmful substances that in turn cause a loss of productivity of the ecosystems. Certain pollutants, even though present in very small concentrations in the soil and surrounding water, have potential to be taken up by various microorganisms, plants, animals, and ultimately human beings. These pollutants may accumulate and concentrate in the food chain by several thousand times through a process referred to as biomagnification.

Urban sewage, because of its nutrient values and source of organic carbon in soils, is increasingly being disposed to

Table 1 Industries, land uses, and associated chemicals contributing to NPSP.

Industry	Type of chemical	Associated chemicals
Agricultural activities	Metals/metalloid	Cd, mercury, arsenic, selenium
	Non-metals	Nitrate, phosphate, borate
	Salinity/sodicity	Sodium, chloride, sulfate, magnesium, alkalinity
	Pesticides	Range of organic and inorganic pesticides including arsenic, copper, zinc, lead, sulfonylureas, organochlorine, organophosphates, etc., salt, geogenic contaminants (e.g., arsenic and selenium)
Automobile and industrial emissions	Irrigation	Sodium, chloride, arsenic, selenium
	Dust	Lead, arsenic, copper, Cd, zinc, etc.
	Gas	Sulfur oxides, carbon oxides
	Metals	Lead and lead organic compounds
Rain water	Organics	Polyaromatic hydrocarbons, polychlorbiphenyls, etc.
	Inorganic	Sulfur oxides, carbon oxides acidity, metals, and metalloids

Source: From Barzi, Naidu, et al.^[4]

land. The contaminants present in sewage sludge (nutrients, heavy metals, organic compounds, and pathogens), if not managed properly, could potentially affect the environment adversely. Dumping of radioactive waste (e.g., radium, uranium, and plutonium) onto soil is more complicated because these materials remain active for thousands of years in the soil and thus pose a continued threat to the health of the ecosystem.

Industrial wastes, improper agricultural techniques, municipal wastes, and use of saline water for irrigation under high evaporative conditions result in the presence of excess soluble salts (predominantly sodium and chlorine ions) and metalloids such as selenium and arsenic in soils. Salinity and sodicity affect the vegetation by inhibiting seed germination, decreasing permeability of roots to water, and disrupting their functions such as photosynthesis, respiration, and synthesis of proteins and enzymes.

Some of the impacts of soil pollution migrate a long way from the source and can persist for some time. For example, suspended solids can increase water turbidity in streams, affecting benthic and pelagic aquatic ecosystems, filling reservoirs with unwanted silt, and requiring water treatment systems for potable water supplies. P attached to soil particles, which are washed from a paddock into a stream, can

dominate nutrient loads in streams and downstream water bodies. Consequences include increases in algal biomass, reduced oxygen concentrations, impaired habitat for aquatic species, and even possible production of cyanobacterial toxins, with serious impacts for humans and livestock consuming the water. Where waters discharge into estuaries, N can be the limiting factor for eutrophication; estuaries of some catchments where fertilizer use is extensive have suffered from excessive sea grass and algal growth.

More insidious is the leaching of nutrients, agricultural chemicals, and hydrocarbons to groundwater. Incremental increases in concentrations in groundwater may be observed over long periods of time resulting in initially potable water becoming undrinkable and then some of the highest valued uses of the resource may be lost for decades. This problem is most severe on tropical islands with shallow relief and some deltaic arsenopyrite deposits, where wells cannot be deepened to avoid polluted groundwater because underlying groundwater is either saline or contains too much As.

SAMPLING FOR NPSP

The sampling requirements of NPSP are quite different from those of the point source contamination. Typically, the sampling is required to give a good estimate of the mean level of pollution rather than to delineate areas of pollution. In such a situation, sampling is typically carried out on a regular square or a triangular grid. Furthermore, gains may be possible by using composite sampling.^[5] However, if the pollution is patchy, other strategies may be used. One such strategy is to divide the area into remediation units and to sample each of these. The possibility of movement of the pollutant from the soil to some receptor (or asset) is assessed, and the potential harm is quantified. This process requires an analysis of the bioavailability of the pollutant, pathway analysis, and the toxicological risk. The risk analysis is then assessed and decisions are then made as to how the risk should be managed.

MANAGEMENT AND OR REMEDIATION OF NPSP

The treatment strategies used for managing NPSP are generally those that modify the soil properties to decrease the bioavailable contaminant fraction. This is particularly so in the rural agricultural environment where soil–plant transfer of contaminants is of greatest concern. Soil amendments commonly used include those that change the ion-exchange characteristics of the colloid particles and those that enhance the ability of soils to sorb contaminants. An example of NPSP management includes the application of lime to immobilize metals because the solubility of most heavy metals decreases with increasing soil pH. However, this approach is not applicable to all metals, especially those that form oxyanions—the bioavailability of such species

increases with increasing pH. Therefore, one of the prerequisites for remediating contaminated sites is a detailed assessment of the nature of contaminants present in the soil. The application of a modified aluminosilicate to a highly contaminated soil around a zinc smelter in Belgium was shown to reduce the bioavailability of metals thereby reducing the Zn phytotoxicity.^[6] The simple addition of rock phosphates to form lead (Pb) phosphate has also been demonstrated to reduce the bioavailability of Pb in aqueous solutions and contaminated soils due to immobilization in the metal.^[7] Nevertheless, there is concern over the long-term stability of the processes. The immobilization process appears attractive given that there are very few cheap and effective *in situ* remediation techniques for metal-contaminated soils. A novel, innovative approach is using higher plants to stabilize, extract, degrade, or volatilize inorganic and organic contaminants for *in situ* treatment (cleanup or containment) of polluted topsoils.^[8]

PREVENTING WATER POLLUTION

The key to preventing water pollution from the soil zone is to manage the source of pollution. For example, nitrate pollution of groundwater will always occur if there is excess nitrate in the soil at a time when there is excess water leaching through the soil. This suggests that we should aim to reduce the N in the soil during wet seasons and the drainage through the soil. Local research may be needed to demonstrate the success of best management techniques in reducing nutrient, sediment, metal, and chemical exports via surface runoff and infiltration to groundwater. Production figures from the same experiments may also convince local farmers of the benefits of maintaining nutrients and chemicals where needed by a crop rather than losing them off site and facilitate uptake of best management practices.

GLOBAL CHALLENGES AND RESPONSIBILITY

The biosphere is a life supporting system to the living organisms. Each species in this system has a role to play and thus every species is important and biological diversity is vital for ecosystem health and functioning. The detection of hazardous compounds in Antarctica, where these compounds were never used or no man has ever lived before, indicates how serious is the problem of long-range

atmospheric transport and deposition of these pollutants. Clearly, pollution knows no boundaries. This ubiquitous pollution has had a global effect on our soils, which in turn has been affecting their biological health and productivity. Coupled with this, over 100,000 chemicals are being used in countries throughout the world. Further focus has been on the endocrine disruptor chemicals that mimic natural hormones and do great harm to animal and human reproductive cycles.

These pollutants are only a few examples of contaminants that are found in the terrestrial environment.

Pollution: Organic and Inorganic

A. Paul Schwab

Department of Agronomy, Purdue University, West Lafayette, Indiana, U.S.A.

Abstract

This entry focuses on pollutants that have anthropogenic origins and addresses organic and inorganic chemicals. Organic contaminants can include pesticides, solvents, preservatives, and petroleum products. Inorganic pollutants include heavy metals, non-metals, metalloids, radionuclides, and simple soluble salts. Whether the source of the contaminants is natural or anthropogenic, an understanding of the chemistry, toxicity, and bioavailability is crucial in responding to soil pollution.

INTRODUCTION

A soil pollutant can be broadly defined as any chemical or other substance that either is not normally found in soil or is present at high enough concentrations to be harmful to any living organisms.^[1] This very general definition could be applied to man-made (anthropogenic) as well as naturally occurring constituents. This entry will focus only on those pollutants that have anthropogenic origins and will address carbon-based (organic) and non-carbonaceous (inorganic) chemicals. Organic contaminants can include pesticides, solvents, preservatives, and petroleum products. Inorganic pollutants include heavy metals [e.g., lead (Pb) and mercury (Hg)], non-metals (selenium), metalloids [arsenic (As) and antimony (Sb)], radionuclides, and simple soluble salts (sodium chloride). Whether the source of the contaminants is natural or anthropogenic, an understanding of the chemistry, toxicity, and bioavailability is crucial in responding to soil pollution.

ORGANIC POLLUTANTS

Thousands of organic chemicals exist in nature, and many are acutely toxic as well as carcinogenic. When discussing toxic organic chemicals in soils, we normally focus on those pollutants resulting from human activities because their release has the potential to be controlled. Typical synthetic organic pollutants include fuels, lubricants, herbicides, fungicides, insecticides, solvents, and propellants.

Soil Contamination by Organic Chemicals

Organic chemicals can find their way into the soil accidentally through spills, leaking storage tanks, and unintentional discharges. However, not all soil pollution is accidental. More than one-half million metric tons of pesticides are used annually, the majority of which are used on agricultural fields.^[1] Approximately, 20,000 metric tons of

pesticides are used in non-agricultural applications including railroad right-of-way weed control, turf, and horticulture. Although many pesticides do not persist in soils, others have been studied extensively because of their potential negative impacts. Chlordane (termite control), dichlorodiphenyltrichloroethane (DDT; mosquitoes), and atrazine (weeds) are excellent examples of organic pesticides that were thought to have human health effects; chlordane and DDT have been banned in the United States, and the banning of atrazine has been debated.

Thousands of organic chemicals are in use, and listing all the specific compounds that contaminate soils is impossible. However, it is possible to discuss the categories of chemicals that are used frequently and are commonly found in soils (Table 1). Pesticides may be the most frequently encountered, and some pesticides are quite toxic. Many of the other classes of the compounds listed are of great concern when found in soil, again due to their potential toxicity to a wide range of organisms.

Potential Impacts of Organic Contaminants

After an organism is exposed to an organic pollutant, a number of antagonistic effects are possible if concentrations are high enough. The most dramatic impact is acute toxicity in which symptoms are quickly apparent and readily identified. At lower concentrations, the impacts become less obvious and take longer to be expressed. For many carcinogens, e.g., decades are required to develop the cancerous tumors. Pathway of exposure, concentrations, and duration of the exposure all dictate the resulting health effects and are essential components of risk analysis.

Bioremediation of Organic Contaminants

Although contamination of soil by organic compounds is an important environmental problem, these pollutants can be removed from the soil through bioremediation. Soil

Table 1 Some classes of organic chemicals found in soils.

Contaminant class	Example(s)	Sources and impacts
Insecticides	DDT, chlordane, diazinon	Used for insect control; DDT and chlordane have serious health effects; diazinon found in water supplies
Herbicides	Atrazine, 2,4-D, 2,4,5-T	Atrazine used on corn; 2,4-D widely used in lawns and agriculture; defoliant 2,4,5-T implicated in health effects in “agent orange”
Fungicides	Benomyl, propiconazole, chlorothalonil	Agricultural fungicides applied to soil directly
Nematicides	Methyl bromide	Used in fumigation of soil to remove nematodes; neurotoxin
Solvents	Trichloroethylene, trichloroethane	Widely used solvents and degreasers; chronic health effects not clear
Fuels	Diesel, kerosene	From spills, leaking tanks. Can lead to groundwater contamination
Polyaromatic hydrocarbons	Chrysene, benzo[a]pyrene	Components of petroleum, particularly after combustion; many of these are carcinogenic
Explosives, propellants	TNT, RDX	Residuals from manufacture the largest source of contamination; acute and chronic toxicities documented

Source: From Schwarzenbach, Gschwend, et al.^[2] and Evangelou.^[3]

microorganisms have a remarkable capacity to degrade organic contaminants. Degradation can be direct, using the organics as a source of energy and carbon, or indirect in which the compounds are cometabolized by organisms seeking similar compounds. End products can be CO₂(g) after total mineralization, alteration, and humification, or incorporation into the microbial biomass. (See the entry *Pollution: Persistent Organic*, p. 1771.)

INORGANIC POLLUTANTS

Inorganic pollutants are those contaminant compounds that do not contain carbon and include the acutely toxic heavy metals, As, radioactive elements, and the far less toxic soluble salts. Although all elements are naturally occurring, thousands of inorganic compounds are formed only through human activities. Some are highly toxic in minute amounts, but all can be harmful when concentrations are high enough.

Classes of Inorganic Pollutants and Concentration Ranges

As with organic pollutants, there are thousands of inorganic contaminants, and they are found over a wide range of concentrations. For discussion, it is convenient to group them in classes (Table 2) consistent with the periodic table. Metals include Pb, zinc (Zn), nickel (Ni), and cadmium (Cd), and their typical soil concentrations vary over a wide range, as the concentrations considered anomalous. Most metals in soils occur as the free cations in solution and in the solid phase. Nearly all metals can have toxic effects on humans although some metals (such as Zn) require high concentrations for toxicity. Metalloids, including As and Sb, generally occur in soil solution and solid phases as oxyanions (such as AsO₄³⁻), resulting in a significantly different chemical behavior than the metals. Metalloids can be highly toxic. Soluble salts are typical inorganic species that, in normal concentrations, do not constitute a health or environmental threat. Typical salts are sulfates, chlorides, and

Table 2 Inorganic contaminants in soil, their typical ranges found in uncontaminated soils, and those concentrations considered to be unusual.

Contaminant	Sources and impacts	Typical range in soil (mg/kg)	Extreme concentrations (mg/kg)
Metals			
Pb, Zn, Cd, Cu, Ni, Ba, Sr, Mn, Cr	Mining, smelting, electroplating	0.1–1,000	25 to >10,000 (metal dependent)
Metalloids			
As, B, Ge, Sb	Industrial activities, smelting	<0.1–100	>50
Non-metals			
Se, I, P, S	Manufacturing, processing	<0.1–1,000	Up to 2,000 (element dependent)
Soluble salts			
Halides, alkalis, alkaline earths, sulfates, nitrates	Mining, manufacturing, petroleum extraction, natural sources	<500	>1,000

Source: From Evangelou^[3] and McBride.^[4]

nitrate of calcium, magnesium, potassium, and sodium. These components are always present in soil and do not constitute an environmental problem until concentrations become excessive (Table 2).

Pathways of Contamination

Once in the soil organic and inorganic pollutants can follow many pathways to the target organisms.^[5] For all contaminants, the direct consumption of contaminated soil can be an important mechanism of exposure for soilborne organisms, grazing mammals that also consume the soil, and humans. For some pollutants, the direct soil consumption is the only means of exposure if they have very low mobility and low bioavailability, e.g., Pb and 5- or 6-ring polyaromatic hydrocarbons.

There are approximately eight pathways by which contaminants in soil can reach humans as the target organism.^[5] Half of the mechanisms involve plant uptake and subsequent consumption of the plants. Most anionic inorganic species are readily assimilated by plants, as are many cationic species. However, some inorganic species form highly insoluble solid phases or are otherwise non-bioavailable, and they are not translocated with the plant. For non-ionic organic species, plant uptake is a function of water solubility and hydrophobicity/lipophilicity. Compounds with intermediate lipophilicity are most suitable for plant uptake. Once the pollutants are in the plant, organisms that consume the vegetation may be exposed to the pollutant, and some of the contaminants are passed along the food chain.

Other pathways of exposure include movement of the contaminant from the soil to the water, air, or becoming airborne on dust/direct volatilization. All of these mechanisms have been shown to contribute to negative health effects. Drinking contaminated water is one of the better known pathways. If the drinking water originates from groundwater, then the pollutants must be soluble in water and readily percolate through the soil and into the groundwater. When surface water is used for drinking, the transport mechanism can be movement of dissolved contaminant in the water, or contaminants may be adsorbed onto the suspended sediment in the soil runoff. Virtually, every soil pollutant can be transported by this mechanism, and only careful control of runoff water and sediments can avoid this problem.

Direct volatilization from the soil into the air is important for a limited number of contaminants, but when the volatilization of a potentially compound or element occurs, exposure is directly through the lungs. Hg is a well-known, volatile metal, and the direct inhalation of high concentrations of gaseous Hg or dimethyl Hg can be poisonous. The inhalation of airborne, contaminated particles is a more frequent occurrence but less insidious. After inhalation, contaminants must be released from the dust before they can be assimilated. The inhalation of contaminated particulates can be reduced possibly through standard soil erosion measures, such as establishing wind breaks and adequate plant cover on contaminated soils.

Soil Remediation Options for Inorganic and Organic Pollutants

The best approach to keeping soil free from contamination is prevention. When this approach fails, removing the contaminants may be necessary, and many options are available.^[6] One of the most commonly used approaches is to excavate the soil and bury it in a hazardous waste landfill. Soils may be incinerated to burn off organic pollutants and to volatilize metals. Soil washing/leaching procedures are available in which the soil is exposed to a solvent that can dissolve that contaminants. The solutions of chelating agents can be effective in the soil washing of metals, and organic solvents can be used to extract organic pollutants. Other approaches include *in situ* vitrification (melting the soil into a block of glass using heat) and chemical immobilization. In all these cases, considerable waste is generated, and the soil is usually lost as a viable resource.

Less destructive approaches are often preferred because the soil is not seriously altered or destroyed, and the techniques are often less expensive. Electrokinesis or electromigration involves applying an electrical potential to the soil and forcing metal ions to migrate to the electrodes. An evolving technology is the use of higher plants to remove contaminants from soil, and this technique is called phytoremediation.^[7,8] For inorganic contaminants, the pollutants are physically removed from the soil. Organic contaminants can be taken up by the plants, degraded in the soil, or volatilized. Electrokinesis and phytoremediation leave the soil as a productive resource, but they take longer than some of the more aggressive alternatives.

Abstract

Biodegradation is the primary dissipation pathway for most organic pollutants in soils. Three prevalent factors related to chemical structure that commonly inhibit the biodegradation of organic pollutants are as follows: 1) inherent susceptibility to enzymatic attack; 2) bioavailability; and 3) nutrient availability. Inherently recalcitrant xenobiotic chemicals (synthetic chemicals with no natural analogs) can persist in environments that lack sufficient numbers of microorganisms with the necessary catabolic pathways. However, the capacity of soil microbial communities to degrade toxic chemicals can increase with repeated chemical exposure. This suggests that the genetic potential to metabolize the chemical is initially present and the capacity to degrade the pollutant could be realized through community adaptation. Understanding the biological fate of these hazardous substances is of critical importance for the protection of human and ecosystem health.

MOLECULAR RECALCITRANCE

Many toxic organic chemicals are intrinsically stable (i.e., recalcitrant) in natural environments due to their fundamental structural properties. The structure of a compound can influence its stability by: 1) inhibiting its susceptibility to enzymatic attack or 2) causing favorable interactions (i.e., sorption) with the soil matrix that result in rate-limited mass transfer between the soil and aqueous phases thus reducing the amount of contaminant that is available for microbial metabolism.

Electrophillic Attack by Oxygenase Enzymes

Several generalizations can be made regarding the chemical structure and susceptibility to enzymatic attack involving two key mechanisms: steric hindrance and electron distribution effects. Under aerobic conditions (oxygen present), many xenobiotic compounds, especially aromatic and aliphatic hydrocarbons can be transformed by the electrophilic addition of oxygen by a class of enzymes known as oxygenases. These enzymes produce an electrophilic form of oxygen at the enzyme active site that subsequently attacks electron-dense sites on the substrate molecule.^[1] In the case of aromatic ring structures, electron-withdrawing substituents, such as halogens, lower the electron density in the ring, rendering it less susceptible to attack by oxygenase enzymes. Conversely, electron-donating substituents such as alkyl groups increase both the electron density in the ring and the oxygenase-mediated reactions. A classic example

of the electronic effects on enzymatic reaction rates is the relative rate of transformation of the herbicide 2,4-D compared to its structural analog 2,4,5-T (Fig. 1). These two molecules are identical with the exception of an additional chlorine atom in position five on the aromatic ring of 2,4,5-T. Addition of this chlorine atom inhibits the electrophilic attack of the acetic acid side chain and dramatically increases the stability of this compound relative to 2,4-D, in natural environments. Halogen substitution of aromatic and aliphatic compounds in key positions can not only block metabolism, producing dead-end metabolites, but also can yield products (e.g., acyl halides) that are lethal to the microorganism.^[1] Another classic example is that of polychlorinated biphenyls and pentachlorophenol (PCP). Biological degradation of these compounds decreases dramatically as the degree of halogenation increases (Fig. 1).

Increasing the degree of halogenation generally stabilizes the organic compounds in aerobic environments. Under anaerobic conditions (oxygen absent), however, these chemicals can be transformed via reductive processes. Reductive reactions usually result in detoxification of the compound and in some cases are involved in the energy-yielding metabolism of some organisms. In such cases, the organism directly transfers electrons (reducing equivalents) from an electron donor such as lactate, acetate, or H₂(g) to the halogenated compound. This terminal electron accepting process is a form of respiration and is analogous to oxidation of carbon substrates using oxygen as an electron acceptor.

Fig. 1 Examples of persistent organic chemicals and their more degradable structural analogs illustrating the effect of various functional groups on biodegradability.

Hydrolytic Reactions

Microorganisms can degrade organic pollutants using hydrolytic reactions.^[1] Enzymes mediating these reactions are generally referred to as hydrolases and act by replacing substituents on the substrate with water. In these reactions, water acts as a nucleophile attacking centers of positive charge on the substrate molecule. Because oxygen does not participate in the reaction, hydrolytic transformations can occur in aerobic or anaerobic environments. Functional groups commonly occurring in many pesticides that are susceptible to hydrolytic attack include amides, esters, carbamates, C-halogen bonds, and sulfonyl ureas to name a few.

Steric Hindrance

Steric hindrance is another mechanism related to chemical structure that can influence enzymatic reactions. The addition of functional groups alters the structure in such a way that it is no longer recognized by the enzyme. Common examples of steric hindrance include highly branched aliphatic compounds or substituents, polycyclic aromatic hydrocarbons (PAHs), and various polymers. As the molecular weight of the substrate increases by branching, polymerization, or addition of fused aromatic rings, susceptibility to enzymatic attack decreases (Fig. 1).

BIOAVAILABILITY

Sorption and Sequestration

Removal of contaminants from the bulk soil aqueous phase can limit their bioavailability to microorganisms,^[2] thus reducing the degradation rate. The reduction of aqueous phase contaminant concentrations can result from a variety of processes that are primarily a function of a chemical's properties and soil characteristics such as clay and organic matter content. These processes include slow dissolution of the contaminant solid or liquid phase,^[3] slow diffusion and sequestration in soil nanopores,^[4] soil sorption (either adsorption or partitioning),^[5] and partitioning of the contaminant in a non-aqueous phase liquid (NAPL; Fig. 2).^[6] Ionizable functional groups on various organic acids and bases (e.g., 2,4-D, atrazine, and quinoline) result in pH-dependent charge of these molecules that can enhance or reduce interaction with sorption sites on soil surfaces. Hydrophobic interactions of non-polar organic compounds, primarily with soil organic matter, are greater for molecules

Fig. 2 Diagram illustrating interactions of solute molecules with the soil matrix resulting in a reduction in bioavailability to microorganisms. Rate limited processes depicted in the figure include sorption-desorption via electrostatic or hydrophobic interactions, entrapment and slow diffusion through nano/micropores, and release of solute from the soil matrix by interactions with surfactant micelles.

with low water solubility (aromatic compounds with alkyl or halide substituents).

Data regarding sorption-limited biodegradation in soils and sediments suggest the existence of available and unavailable compartments. However, the concentration of contaminant in these two pools does not strictly correspond to the soil aqueous and solid phases, respectively. Substrate localized in the “unavailable” compartment(s) may be an exploitable resource for appropriately adapted microorganisms. For example, differences have been observed in the bioavailability of sorbed PAHs naphthalene- and phenanthrene-degrading bacteria.^[7] Bacterial attachment at the interface between non-NAPL; a class of liquid organic contaminants such as solvents and fuels) and water is known to influence the uptake of NAPL and NAPL-partitioned organic compounds.^[8] Little is known about the role of attachment in the biodegradation of soil-sorbed pollutants. However, the ability of microorganisms to utilize surface accumulated substrates in dilute media has been recognized since the early 1940s.^[9] Biodegradation of soil-sorbed phenanthrene varied substantially between two PAH-degrading bacteria with differing cell surface properties.^[10] These studies indicate that bioavailability may be species-dependent and suggest that cellular attachment and as yet unidentified adaptations may allow some species greater access to sorbed pollutants.

Enhancing Bioavailability

Increasing the degradation of sorbed, trapped, or insoluble pollutants focused on enhancing the contaminant release from the soil matrix through the addition of cosolvents and surfactants. Enhancement and inhibition of biodegradation in the presence of surfactants have been reported. In general, enhanced degradation is attributed to enhanced solubility,^[3] an increase in the interfacial surface area between immiscible fluids,^[11] or enhanced desorption (Fig. 2).^[12] Inhibition of biodegradation can result from surfactant toxicity, sequestration of the contaminant within surfactant micelles,^[13] or preferential utilization of the surfactant as a substrate.^[11] Understanding how microbes enhance desorption or gain access to sorbed substrates is paramount to reducing the persistence of sorbed organic pollutants.

NUTRIENT AVAILABILITY

Effect of Added Nutrients on Hydrocarbon Degradation

Most soil and subsurface environments are limited in available carbon for microbial growth. However, in hydrocarbon contaminated soils, the ratio of reduced C to other nutrients is very large and as a result one or more nutrients other than C may become rate-limiting factors for contaminant biodegradation. Addition of inorganic nutrients usually

enhances hydrocarbon biodegradation. This approach is frequently considered to stimulate bioremediation of petroleum contaminated environments. Optimal ranges of C/N/P/S ratios vary enormously but a C/N/P ratio of 100:10:1 is generally accepted as optimal for hydrocarbon biodegradation in most environments. Inorganic salts such as ammonium phosphate are commonly used as nutrient fertilizers in hydrocarbon contaminated environments. Inorganic salts are inexpensive and provide nutrients in bioavailable forms, but in some situations these fertilizers can become diluted or washed out of the contaminated zone and therefore do not provide a long-term supply of the limiting nutrient(s). This is particularly a concern in near shore and saturated environments. In other cases, use of these fertilizers can lead to rather dramatic changes in pH or result in osmotic stress that can adversely affect biodegradation rates. These problems can sometimes be overcome by using organic nutrient sources with low C/N and C/P ratios such as urea, oleophilic forms of N and P, or a variety of other slow-release fertilizers.^[14]

Accelerated biodegradation in response to fertilization is frequently reported in hydrocarbon-contaminated soils and aquifer sediments.^[15] Some studies, however, have observed no increase or an inhibition in degradation rates.^[16] These contradictory results suggest that the response of the microbial community to manipulation of various environmental factors to optimize biodegradation is site specific and reflects the complex nature of heterogeneous systems such as soils.^[17]

Organic Chemicals That Are Macronutrient Sources

Ammonia is almost invariably the preferred N source for most bacteria. However, in natural environments ammonia is not always available, and bacteria have evolved the ability to use a wide array of organic and inorganic compounds as N sources. From a pragmatic viewpoint, coordinated regulation of degradative pathways and N-assimilatory pathways makes sense if the organic chemical in question is a poor carbon and energy source but potentially a good N source.

Biodegradation of a N-Containing Herbicide

Unlike homocyclic aromatic compounds such as 2,4-D, atrazine (Fig. 1) can serve as a C and N source for some microorganisms. Hence the level of induction and expression of the atrazine-degrading genotype in soil microorganisms is likely to be affected by the C and N status in soils. Atrazine has a low C/N ratio (8:5) and its complete mineralization results in release of excess N. Therefore, atrazine is potentially a good N source and its degradation is likely to be favored in N-limited soils. Addition of inorganic fertilizers to soils has been shown to inhibit atrazine mineralization.^[18,19] The general suppression of atrazine

mineralization in the presence of exogenous nitrogen suggests that regulation and expression of atrazine degradation genes in soil microbial communities are linked to the N status of soil. Atrazine and its N-heterocyclic derivatives are apparently substrates for a complex pathway that may be catabolic as well as linked to assimilatory pathways of C and N. A study with ^{15}N -ring-atrazine has definitively shown that atrazine-N is incorporated into the biomass of several bacterial cultures known to mineralize atrazine.^[19] Evidence for a regulatory linkage between atrazine catabolism and N assimilation has also been observed in an atrazine-mineralizing soil bacteria.^[19,20] Given the apparent negative correlation between atrazine degradation rates and soil N levels, perhaps the majority of soil bacteria capable of utilizing triazine-N can repress expression of the degradative pathway enzymes in favor of more readily available sources of N.

MICROBIAL ECOLOGY AND BIODEGRADATION

Soil is perhaps the most biologically diverse and abundant ecosystem in the biosphere. A few grams of topsoil may contain 5000–15,000 different microbial species. Only 0.1–1% of this biodiversity has been cultured and studied in the laboratory. Understanding of pollutant biodegradation is largely based on the study of microorganisms obtained via classical enrichment techniques. However, since these organisms were isolated under very selective conditions and represent less than 0.1% of the biodiversity of soil, they may not be representative of the full genetic biodegradation potential of soil communities and may play only a minor role in the detoxification of contaminated soil. To more fully understand environmental processes mediated by microorganisms, various culture-independent methodologies, based on the analysis of soil genomic DNA, are becoming widely used. Many of these approaches are based on the detection of 16S rRNA genes (16S rDNA) from community members that do not grow well in the laboratory.

One such technique amenable to ecological studies is denaturing gradient gel electrophoresis (DGGE). This DNA fingerprinting technique allows separation of DNA fragments of similar size but different sequence composition.^[21] When applied to microbial community analysis, conserved 16S rDNA sequences are used as primers to amplify community DNA. The resulting mixture of PCR products is then separated by DGGE. The result is a pattern of bands that roughly corresponds to the number of predominant members in a microbial community. Statistical analysis of banding patterns can then be used to monitor changes in the structure of microbial communities or to compare communities in different environments. The selection of the PCR primers used to amplify community DNA determines the relative breadth or narrowness of community members targeted for analysis. In some instances,

DNA fragments isolated from DGGE bands can be sequenced to identify phylogenetically the organisms represented by that particular band.

This approach has been used to characterize microbial communities in soils with and without prior atrazine exposure histories (H and NH soil, respectively) and different C/N ratios. The DNA fingerprints were then related to atrazine mineralization capacity in the acclimated soils (soils exposed to three atrazine amendments in a lab acclimation study; Fig. 3). The banding patterns revealed highly complex microbial communities. Although several shared bands were observed, the DNA fingerprints of the H and NH soils showed two distinctly different communities (lanes E and M). The bands (representing distinct phylotypes) that intensified in response to atrazine amendment in the H soil were different from those that intensified in the NH soil. For example, band 1 in the H soil was not present in the NH soil and bands 2 and 3 were present in the NH soil amended with atrazine but absent in the H soil. In soils amended with atrazine + NH_4NO_3 (low C/N), several bands in the H soil became more intense (bands 4–6, lane K). These bands were absent in the corresponding NH soil (lane C). Interestingly, band 4 was even more

Fig. 3 PCR amplified 16S rDNA fingerprint of microbial communities obtained using DGGE analysis of DNA extracted from amended NH (A–F) and H soils (I–N). Soil amendments include: non-amended field soil (F and N), water control (E and M), atrazine (D and L), atrazine + NH_4NO_3 (C and K), atrazine + acetate (B and J), and atrazine + acetate + NH_4NO_3 (A and I). A pure bacterial strain, isolate P5-2 was used as a positive control (G) and a water control (H) was also included.

intense in the atrazine + acetate (high C/N) treated soil while bands 5 and 6 were absent. In general, the communities in the H and NH soils responded quite differently to the various amendments (i.e., variations in C/N ratio). Presumably, the organisms represented by these bands in the DGGE gel play a very significant role in atrazine degradation in this soil.

Abstract

Environmental pollution is one of the foremost ecological challenges. Pollution is an offshoot of technological advancement and overexploitation of natural resources. From the standpoint of pollution, the term environment primarily includes air, land, and water components including landscapes, rivers, parks, and oceans. Pollution can be generally defined as an undesirable change in the natural quality of the environment that may adversely affect the well-being of humans, other living organisms, or entire ecosystems either directly or indirectly. Although pollution is often the result of human activities (anthropogenic), it could also be due to natural sources such as volcanic eruptions emitting noxious gases, pedogenic processes, or natural change in the climate. Where pollution is localized, it is described as point source (PS). Thus, PS pollution is a source of pollution with a clearly identifiable point of discharge that can be traced back to the specific source such as leakage of underground petroleum storage tanks or an industrial site.

INTRODUCTION

Some naturally occurring pollutants are termed geogenic contaminants, and these include fluorine (F), selenium, arsenic (As), lead, chromium, fluoride, and radionuclides in the soil and water environment. Significant adverse impacts of geogenic contaminants (e.g., As) on environmental and human health have been recorded in Bangladesh, West Bengal, India, Vietnam, and China. The presence of geogenic cadmium and the implications to crop quality in Norwegian soils are also studied.^[1]

The terms contamination and pollution are often used interchangeably but erroneously. Contamination denotes the presence of a particular substance at a higher concentration than would occur naturally, and this may or may not have harmful effects on human or the environment. Pollution not only refers to the presence of a substance at higher level than would normally occur but also is associated with some kind of adverse effect.

NATURE AND SOURCES OF CONTAMINANTS

The main activities contributing to point source (PS) pollution include industrial, mining, agricultural, and

commercial activities as well as transport and services (Table 1). Uncontrolled mining, manufacturing, and disposal of wastes inevitably cause environmental pollution. Military land and land used for recreational shooting are also important sites of PS contamination. The contaminants associated with such activities are listed in Table 1. Contamination at many of these sites appears to have resulted because of lax regulatory measures prior to the establishment of legislation protecting the environment.

CONTAMINANT INTERACTIONS IN SOIL AND WATER

Inorganic Chemicals

Inorganic contaminant interactions with colloid particulates include the following: adsorption–desorption at surface sites, precipitation, ion exchange with clay minerals, binding by organically coated particulate matter or organic colloidal material, or adsorption of contaminant ligand complexes. Depending on the nature of contaminants, these interactions are controlled by solution pH and ionic strength of soil solution, nature of the species, dominant

Table 1 Industries, land uses, and associated chemicals contributing to PS and non-PS pollution.

Industry	Type of chemical	Associated chemicals
Airports	Hydrocarbons	Aviation fuels
	Metals	Particularly aluminum, magnesium, chromium
Asbestos production and disposal	Asbestos	
Battery manufacture and recycling	Metals	Lead, manganese, zinc, cadmium, nickel, cobalt, mercury, silver, antimony
	Acids	Sulfuric acid
Breweries/distilleries	Alcohol	Ethanol, methanol, esters
Chemicals manufacture and use	Acid/alkali	Mercury (chloralkali), sulfuric, hydrochloric and nitric acids, sodium and calcium hydroxides
	Adhesives/resins	Polyvinyl acetate, phenols, formaldehyde, acrylates, phthalates
	Dyes	Chromium, titanium, cobalt, sulfur and nitrogen organic compounds, sulfates, solvents
	Explosives	Acetone, nitric acid, ammonium nitrate, pentachlorophenol, ammonia, sulfuric acid, nitroglycerine, calcium cyanamide, lead, ethylene glycol, methanol, copper, aluminum, bis(2-ethylhexyl) adipate, dibutyl phthalate, sodium hydroxide, mercury, silver
	Fertilizer	Calcium phosphate, calcium sulfate, nitrates, ammonium sulfate, carbonates, potassium, copper, magnesium, molybdenum, boron, cadmium
	Flocculants	Aluminum
	Foam production	Urethane, formaldehyde, styrene
	Fungicides	Carbamates, copper sulfate, copper chloride, sulfur, chromium
	Herbicides	Ammonium thiocyanate, carbonates, organochlorines, organophosphates, As, mercury
	Paints	
	Heavy metals	As, barium, cadmium, chromium, cobalt, lead, manganese, mercury, selenium, zinc

(Continued)

Table 1 Industries, land uses, and associated chemicals contributing to PS and non-PS pollution. (Continued)

Industry	Type of chemical	Associated chemicals
	General	Titanium dioxide
	Solvent	Toluene, oils natural (e.g., pine oil) or synthetic
	Pesticides	As, lead, organochlorines, organophosphates
	Active ingredients	Sodium, tetraborate, carbamates, sulfur, synthetic pyrethroids
	Solvents	Xylene, kerosene, methyl isobutyl ketone, amyl acetate, chlorinated solvents
	Pharmacy	Dextrose, starch
	General/solvents	Acetone, cyclohexane, methylene chloride, ethyl acetate, butyl acetate, methanol, ethanol, isopropanol, butanol, pyridine methyl ethyl ketone, methyl isobutyl ketone, tetrahydrofuran
	Photography	Hydroquinone, pheidom, sodium carbonate, sodium sulfite, potassium bromide, monomethyl para-aminophenol sulfates, ferricyanide, chromium, silver, thiocyanate, ammonium compounds, sulfur compounds, phosphate, phenylene diamine, ethyl alcohol, thiosulfates, formaldehyde
	Plastics	Sulfates, carbonates, cadmium, solvents, acrylates, phthalates, styrene
	Rubber	Carbon black
	Soap/detergent	
	General	Potassium compounds, phosphates, ammonia, alcohols, esters, sodium hydroxide, surfactants (sodium lauryl sulfate), silicate compounds
	Acids	Sulfuric acid and stearic acid
	Oils	Palm, coconut, pine, tea tree
	Solvents	
	General	Ammonia
	Hydrocarbons	e.g., BTEX (benzene, toluene, ethylbenzene, xylene)
	Chlorinated organics	e.g., trichloroethane, carbon tetrachloride, methylene chloride

cation, and inorganic and organic ligands present in the soil solution.^[3]

Organic Chemicals

The fate and behavior of organic compounds depend on a variety of processes including sorption–desorption, volatilization, chemical and biological degradation, plant uptake, surface runoff, and leaching. Sorption–desorption and degradation (both biotic and abiotic) are perhaps the two most important processes as the bulk of the chemicals is either sorbed by organic and inorganic soil constituents, or chemically or microbially transformed/degraded. The degradation is not always a detoxification process. This is because in some cases the transformation or degradation process leads to intermediate products that are more mobile, more persistent, or more toxic to non-target organisms. The relative importance of these processes is determined by the chemical nature of the compound.

IMPLICATIONS TO SOIL AND ENVIRONMENTAL QUALITY

Considerable amount of literature is available on the effects of contaminants on soil microorganisms and their functions in soil. The negative impacts of contaminants on microbial processes are important from the ecosystem point of view, and any such effects could potentially result in a major ecological perturbation. Hence, it is most relevant to examine the effects of contaminants on microbial processes in combination with communities. The most commonly used indicators of metal effects on microflora in soil are as follows: 1) soil respiration; 2) soil nitrification; 3) soil microbial biomass; and 4) soil enzymes.

Contaminants can reach the food chain by way of water, soil, plants, and animals. In addition to the food chain transfer, pollutants may also enter via direct consumption or dust inhalation of soil by children or animals. The

accumulation of these pollutants can take place in certain target tissues of the organism depending on the solubility and nature of the compound. For example, dichlorodiphenyltrichloroethane and polychlorinated biphenyls (PCBs) accumulate in human adipose tissue. Consequently, several of these pollutants have the potential to cause serious abnormalities including cancer and reproductive impairments in animal and human systems.

SAMPLING FOR PS POLLUTION

The aims of the sampling system must be clearly defined before it can be optimized.^[4] The type of decision may be to determine land use, how much of an area is to be remediated, or what type of remediation process is required. Because sampling and the associated chemical and statistical analyses are expensive, careful planning of the sampling scheme is therefore a good investment. One of the best ways to achieve this is to use the ancillary data that are available. These data could be in the form of emission history from a stack, old photographs that give details of previous land uses, or agricultural records. Such data can at least give qualitative information.

As discussed before, PS pollution will typically be airborne from a stack or waterborne from some effluent such as tannery waste, cattle dips, or mine waste. In many cases, the industry will have modified its emissions (e.g., cleaner production) or point of release (increased stack height); hence, the existing pattern of emission may not be closely related to the historic pattern of pollution. For example, liquid effluent may previously have been discharged into a bay, but that effluent may now be treated and perhaps discharged at some other point. Typically, the aim of a sampling scheme in these situations is to assess the maximum concentrations, the extent of the pollution, and the rate of decline in concentration from the PS. Often, the sampling scheme will be used to produce maps of concentration isopleths of the pollutant.

The location of the sampling points would normally be concentrated toward the source of the pollution. A good scheme is to have sufficient samples to accurately assess the maximum pollution and then space additional samples at increasing intervals. In most cases, the distribution of the pollutant will be asymmetric, with the maximum spread down the slope or down the prevailing wind. In such cases, more samples should be placed in the direction of the expected gradient. This is a clear case of when ancillary data can be used effectively. A graph of concentration of the pollutant against the reciprocal of distance from the source is often informative.^[5] Sampling depths will depend on both the nature of the pollution and the reason for the investigation. If the pollution is from dust and it is unlikely to be leached, only surface sampling will be required. An example of this is pollution from silver smelting in

Wales.^[6] In contrast, contamination from organic or mobile inorganic pollutants such as F compounds may migrate well down to the profile, and deep sampling may be required.^[7,8]

ASSESSMENT

In order to assess the impacts of pollution, reliable and effective monitoring techniques are important. Pollution can be assessed and monitored by chemical analyses, toxicity tests, and field surveys. Comparison of contaminant data with an uncontaminated reference site and available databases for baseline concentrations can be useful in establishing the extent of contamination. However, this may not be always possible in the field. Chemical analyses must be used in conjunction with biological assays to reveal site contamination and associated adverse effects. Toxicological assays can also reveal information about synergistic interactions of two or more contaminants present as mixtures in soil, which cannot be measured by chemical assays alone.

Microorganisms serve as rapid detectors of environmental pollution and are thus of importance as pollution indicators. The presence of pollutants can induce the alteration of microbial communities, reduction of species diversity and inhibition of certain microbial processes (organic matter breakdown, mineralization of carbon and nitrogen, enzymatic activities, etc.). A measure of the functional diversity of the bacterial flora can be assessed using ecoplates (see http://www.biolog.com/section_4.html). It has been shown that algae are especially sensitive to various organic and inorganic pollutants and thus may serve as a good indicator of pollution.^[9] A variety of toxicity tests involving microorganisms, invertebrates, vertebrates, and plants may be used with soil or water samples.^[10]

MANAGEMENT AND/OR REMEDIATION OF PS POLLUTION

The major objectives of any remediation process are to 1) reduce the actual or potential environmental threat and 2) reduce unacceptable risks to man, animals, and the environment to acceptable levels.^[11] Therefore, strategies to either manage or remediate contaminated sites have developed largely from the application of stringent regulatory measures set up to safeguard ecosystem function as well as to minimize the potential adverse effects of toxic substances on animal and human health.

The available remediation technologies may be grouped into two categories: 1) *ex situ* techniques that require removal of the contaminated soil or groundwater for treatment either on-site or off-site and 2) *in situ* techniques that attempt to remediate without the

excavation of contaminated soils. Generally, *in situ* techniques are favored over *ex situ* techniques because of 1) reduced costs due to the elimination or minimization of excavation, transportation to disposal sites, and sometimes treatment itself; 2) reduced health impacts on the public or the workers; and 3) the potential for the remediation of inaccessible sites, e.g., those located at greater depths or under buildings. Although *in situ* techniques have been successful with organic contaminated sites, the success of *in situ* strategies with metal contaminants has been limited. Given that organic and inorganic contaminants often occur as a mixture, a combination of more than one strategy is often required to either successfully remediate or manage metal contaminated soils.

GLOBAL CHALLENGES AND RESPONSIBILITY

The last 100 years have seen massive industrialization. Indeed, such developments were coupled with the rapid increase in world population and the desire to enhance economy and food productivity. While industrialization has led to increased economic activity and much benefit to human race, the lack of regulatory measures and appropriate waste management strategies until early 1980s (including the use of agrochemicals) has resulted in the contamination of our biosphere. Continued pollution of the environment through industrial emissions is of global concern. There is, therefore, a need for politicians, regulatory organizations, and scientists to work together to minimize environmental contamination and to remediate contaminated sites. The responsibility to check this pollution lies with every individual and country although the majority of this pollution is due to the industrialized nations. There is a clear need of better coordination of efforts in dealing with numerous forms of PS pollution problems that are being faced globally.

Porosity: Pore Size Distribution

Keith C. Cameron

Soil and Physical Science Group, Lincoln University, Canterbury, New Zealand

Graeme D. Buchan

Centre for Soil and Environmental Quality, Lincoln University, Canterbury, New Zealand

Abstract

The relative arrangement of the soil units (primary particles and aggregates) defines the pore space of the soil. Pore space is essential as it provides the capacity to store water and air as well as enables drainage and root growth. For some soil processes, the total porosity is less important than the pore size distribution; e.g., a sandy soil has a lower total porosity than a clayey soil, but usually drains faster. The ability of a pore to transmit water decreases dramatically with its size. The sandy soil has a higher proportion of large soil pores than the clay and thus drains much faster. Small pores are, however, essential as they provide the ability to store water.

THE SOIL PORE SYSTEM

Structured or aggregated soils are effective “dual porosity” systems. Their porosity can be separated approximately into two components.

1. “Intra-aggregate porosity” is the microscopic pore space created by the geometrical packing of individual soil particles.
2. “Interaggregate porosity” represents the pore space caused by the arrangement of soil aggregates. It is created by biological activity, such as earthworm burrowing and root growth, shrinkage during soil drying, and cultivation of plants.

Definitions

Pore size

Soil particles are normally specified by a single size, the diameter of an equivalent idealized sphere. By contrast, we assume that the soil pore space can be partitioned into a system of idealized cylindrical tubes, each with an equivalent cylinder radius, r . This enables us to link the size of a pore with its ability to attract water by capillary action, as measured by the suction head h (cm) required to empty that pore:

$$h = (2\gamma/r)\cos \alpha \quad (1)$$

where γ is the surface tension, r the pore radius (cm), and α the contact angle.

Fig. 1 shows how soil pore sizes can be classified using either soil micromorphology or the hydraulic properties of soil.

Total porosity, ϵ

This is the ratio of the volume of pores to the total volume of soil

$$\epsilon = \frac{\text{volume of pores}}{\text{total volume of soil}} = \frac{V_p}{V_t} \quad (2)$$

Most soils have their porosity between 0.3 and 0.6, usually expressed as a percentage (i.e., 30% and 60%). Organic soils (e.g., peats) may have porosity up to 90%.

Air-filled porosity, ϵ_a

This is the ratio of the volume of air to the total volume of soil:

$$\epsilon_a = \frac{\text{volume of air}}{\text{total volume of soil}} = \frac{V_a}{V_t} \quad (3)$$

For field soils, an approximate minimum value of ϵ_a required to maintain adequate aeration (especially oxygen supply to respiring roots and microbes) is about 10%, although a range of values from 10% to 25% may occur.^[1]

If ϵ_a is less than 10% at “field capacity,” then soil loosening or drainage is recommended. A desirable ϵ_a for horticultural potting mixes is in the range of 20–25%, which provides rapid drainage and low mechanical impedance for root growth, while the organic matter provides adequate water-holding capacity.^[2]

Fig. 1 Sizes of particles, pores, and biota in soil. (Top to bottom) particle sizes (μm) in the U.S. Department of Agriculture classification; pore sizes defined morphologically by Brewer; pore sizes defined hydraulically, with field capacity (FC, 0.1 bar) defining the lower limit of “drainable porosity,” and permanent wilting point (PWP, 15 bar) defining the limit of “storage pores;” typical sizes (diameters) of roots and microbiota in soil. Root sizes are for cereal crops.

Source: From Brewer^[3] and Gregory.^[4]

Macroporosity

Unfortunately there is no single, clear, or agreed criterion for the definition of “macropores” in soil. The minimum equivalent diameter, d , for macropores reported in the literature ranges between 30 and 3000 μm . Here, we adopt the lower limit and define macroporosity as the fraction of soil volume occupied by pores with $d > 30 \mu\text{m}$. This definition of macroporosity represents the air-filled porosity at field capacity, so that macropores are the “drainable pores” (Fig. 1).

Methods of Measurement

“Total porosity” can be measured by various techniques. The simplest method involves the collection and weighing of undisturbed soil cores of known volume (V_t). The ratio of the mass of dry soil to V_t gives the soil “bulk density,” ρ_b . ϵ is then calculated as follows:

$$\epsilon = 1 - \rho_b / \rho_p \quad (4)$$

where ρ_p is the particle density. For most common soil minerals, $\rho_p = 2.65 \text{ g/cm}^3$, but ρ_p decreases as organic matter increases; e.g., a soil with $\rho_b = 1.3 \text{ g/cm}^3$ and $\rho_p = 2.65 \text{ g/cm}^3$ would have a porosity of 51%.

Porosity can also be measured using a gas pycnometer.^[5] The original method, developed by Torstensson and Eriksson,^[6] is based on Boyle’s law of volume–pressure relationships. An oven-dried soil core is sealed into a gas-tight chamber of the pycnometer, and the air in the chamber

is compressed by a known amount. The porosity is calculated from the difference between the volume of compressed air in the chamber when it contains a soil sample and when it is empty.

Macroporosity depends on the definition chosen for the lower limit of macropore diameter. It can be measured from the soil moisture characteristic (SMC) that specifies where macroporosity may also be measured optically, using image analysis of thin sections of soil. Bullock and Thomasson^[7] in their pioneering work developed techniques for scanning thin sections of soil with a television camera and setting an image analyzer to detect differences in gray-scale indicating solids or pores. The volume and geometrical arrangement of the soil pores can be determined.

PORE SIZE DISTRIBUTION

Pores can be classified according to size or function, as shown in Fig. 1.

The macropores ($d > 30 \mu\text{m}$) are usually air-filled and contain water only when the soil is saturated or partially drained. The smaller pores (micropores, $d < 30 \mu\text{m}$) include the storage pores retaining plant-available water and are generally found within, rather than between the soil aggregates.

Methods of Measurement

Lawrence^[8] reviews techniques for measuring pore sizes in soil. The commonest method is to determine the SMC.

Fig. 2 Comparison of a SMC of a sandy vs. a clay soil.
Source: Adapted from McLaren & Cameron.^[9]

The SMC is the relationship between soil water content θ and the soil matric potential ψ_m (Fig. 2). As ψ_m is negative in unsaturated soil, we drop the negative sign and refer instead to the suction h (refers to $-\psi_m$).

The amount of water retained by the soil over a range of matric potentials can be measured by applying a suction to the soil to overcome the forces of capillarity and adhesion holding the water, using the apparatus shown in Fig. 3. An undisturbed core taken from the field is saturated with water and placed on the porous plate of the “tension table.” When the column of water is level with the soil, all the pores are water-filled. As the column is lowered, increasing suction removes water, first from the larger soil pores, followed by progressively smaller pores. The loss of water at each suction is measured by reweighing the soil core once it has ceased to drain at each particular suction.

The suction (or tension table) technique is limited to suctions less than approximately 10 kPa. Water held at lower matric potentials ($\psi_m < -10$ kPa) must be measured using a “pressure plate” technique.^[5]

The clay soil in Fig. 2 has a higher water content at each matric potential than the sandy soil, because the clay has a finer texture with smaller pores. The sandy soil pores are larger and can be emptied at relatively low suctions. The shape of the curve for the sandy soil reflects the restricted size range of pores, most of which empty around the same suction (e.g., 10 kPa in Fig. 2). The clay soil has a more gradual curve reflecting the more uniform distribution of pore sizes.

Soil structure affects the shape of the moisture release curve at low suctions (e.g., 0 to ca. 10 kPa), because it is the shape and packing of the structural units that mainly define the volume of macropores. Differences between soils at low suctions provide information about the relative drainage and aeration capacities of the soils.

Pore size distribution can also be measured using mercury intrusion porosimetry.^[8] Pressure is used to force mercury into the soil pores. The relationship between applied pressure and the volume of intruded mercury provides the measure of

Fig. 3 Measurement of soil moisture release characteristic using tension table equipment.

Source: Adapted from McLaren & Cameron.^[9]

pore size distribution. Although the method is fast, errors may occur because of the differences in the contact angle of the mercury on different mineral surfaces.^[5]

KEY FUNCTIONS OF THE PORE SYSTEM

Porosity and pore size distribution control a wide range of soil phenomena, including the following:

1. *Water storage in soil.* This is one of the critical soil properties that determine the ability of a soil to sustain plant growth. The amount of water that is stored in a

soil depends not just on the total porosity but also on the pore size distribution.

2. *Transmission characteristics of the soil.* The hydraulic conductivity of the soil controls its drainage rate and its ability to support plant growth. Different size classes of pores perform different functions. Macropore flow controls drainage at or near saturation. Micropore flow regulates the rate of water supply to roots and hence determines the onset of plant water stress. The soil pore system also affects the transport of solutes and particles with the soil solution. For saturated or near-saturated flow, macropores can provide a “preferential” or a “bypass” pathway for water, solutes, or particles. Soil micropores provide a “storage volume” that can protect solutes against leaching. Diffusion of solutes out of soil micropores helps to supply nutrients to plant roots. Soil porosity and pore size distribution control the rate of mass flow and diffusion of soil gases. Plant root respiration requires a constant supply of oxygen and produces carbon dioxide. The soil pore system influences the rate of supply of oxygen at the root surface of the plant and rate of diffusion of carbon dioxide away from the root.
3. *Soil mechanical properties, including penetration resistance, soil consistency, compactibility, and “bearing capacity.”* Plant roots grow through the soil pore system in search of water and nutrients. Although roots are able to expand the diameter of a soil pore, the rate of root growth can be severely limited in a compact soil with low porosity. The greater the porosity of a soil, the more easily it can be compacted, and the more likely it is to yield or deform under stress or load.
4. *Location of biological activity, including migration of worms, nematodes, or pathogens.* Although soil organisms can create their own pores by burrowing through soil, they also utilize the existing pore system.

CONCLUSION

Soil pore space is essential because it provides the capacity to store water and air in the soil as well as enables drainage and root growth through the soil. Soil pore space is defined by the relative arrangements of the soil particles and soil aggregates.

Potassium

Philippe Hinsinger

National Institute of Agronomic Research (INRA), Montpellier, France

Abstract

Potassium (atomic weight = 39.098) is an alkaline metal, as revealed by the etymology of its symbol (K) that derives from the Latin word “kalium” and from the Arabic word “qali” (alkali). K is thus strongly electropositive and always occurs as a monovalent cation. Consequently, its physico-chemistry and speciation are rather simple. K is an abundant alkaline metal cation, reaching a concentration of 26 g kg^{-1} in the earth's crust. It is a major nutrient for all living organisms.

POTASSIUM IN PLANTS

Potassium (K) is the major cation in most plants, occurring at concentrations ranging from 5 to 50 g kg^{-1} , twice as much as calcium (Ca) and slightly less than nitrogen (N).^[1–3] The etymology of its name accounts for the abundance of K in plant-derived ash material (potash). K is involved in a large number of physiological processes: osmoregulation and cation–anion balance, protein synthesis, and activation of enzymes.^[2,3] K is often referred to as “a cation for anions” as it balances the abundant negative charges of inorganic (nitrate) and organic (carboxylates) anions in plant cells. It therefore occurs at large concentrations, 100–200 mM in the cytosol, 5 to 10 times less in the vacuole. Being a major inorganic solute, it plays a key role in the water balance of plants: maintenance of the osmotic potential and turgor pressure involved in cell extension. K-controlled changes in turgor pressure in guard cells are a key process of stomatal opening and closure and hence the regulation of plant transpiration. Many of these physiological roles are related to the high mobility of K at all levels in the plant. This unique, considerable mobility of K in the plant is essentially due to the large permeability of cell membranes to K ions, which arises from the occurrence of a range of highly K selective, low and high affinity ion channels and transporters. These are being increasingly characterized at a molecular level.^[4] Large rates of K uptake can thereby be achieved in plant roots. In addition, K ions can easily be leached out of living plant tissues, as documented for tree foliage that contributes a large flux of K back to the soil via throughfall.^[3] K also rapidly leaves dead roots and other plant debris compared with N and P, which requires hydrolysis of organic molecules. At an agronomic level, the demand for K largely varies with plant species and productivity. The uptake of K essentially occurs during the vegetative stage and can reach values of $10 \text{ kg ha}^{-1} \text{ day}^{-1}$ and above. Depending also on the agricultural practices (removal of straw, for instance), the

amount of K removed with the harvested material will range from $5\text{--}50 \text{ kg ha}^{-1}$ for cereal grains to $50\text{--}500 \text{ kg ha}^{-1}$ for forage, root, and tuber or plantation crops.

POTASSIUM IN SOILS

Among major nutrients, K is usually the most abundant in soils as total K content ranges from 0.1 to 40, with an average of 14 g kg^{-1} .^[1,5] A major proportion of soil K occurs as structural K in feldspars and interlayer K in mica-ceous minerals (Fig. 1).^[1,6,7] Some minor proportion of soil K (usually much less than 1%) is adsorbed on negatively charged soil constituents, namely clay minerals and organic matter. A marginal part is present as free K ions in the soil solution. Bulk soil solution concentrations usually amount to $100\text{--}1000 \mu\text{M}$ (less than 0.01–0.1% of total K). The reason for this rather low concentration of K in the soil solution and hence restricted mobility of K in soils, compared to other metal cations such as sodium (Na) or Ca is related to its selective adsorption onto some clay minerals. Because of its ionic radius and small hydration energy, K ions indeed perfectly fit into the interlayer sites of mica-ceous minerals (micas, illites, and mica-derived clays).^[8] These sites and, to a lesser degree, the sites on the frayed edges of these minerals have thus a considerably larger affinity for K than for other cations, including divalent cations such as Ca or magnesium (Mg; Fig. 2). Clay minerals also bear sites with larger affinity for divalent cations than for monovalent cations such as K. These sites are located on the planar faces of clay minerals and are thus dominant in clays such as kaolins and smectites. They also occur in organic compounds. K is thus much less strongly held in soils dominated by kaolins (tropical soils), sand, or organic matter than in soils dominated by illite–vermiculite clay minerals. Traces of mica-derived clay minerals can dramatically influence the dynamics of soil K as evidenced in tropical soils that are apparently dominated by kaolins.^[9]

Fig. 1 The various forms of soil K and the chemical processes involved in soil K dynamics.

More generally, K dynamic is largely dependent on soil mineralogy that determines both ion exchange and release-fixation processes,^[6,7] i.e., the dynamics of “non-exchangeable K.” The latter is defined as that (major) portion of soil K that cannot be exchanged by ammonium (NH_4) ions. NH_4 ions have the same charge and radius than K ions and can successfully desorb K only from low K-affinity sites. Exchangeable K thus comprise soil solution and easily desorbable K ions. Non-exchangeable K mostly comprise interlayer K (high K-affinity sites) of micaceous minerals and structural K of feldspars (Fig. 1), i.e., 90–99% of total K in many soils. The release of K from feldspars requires a complete and irreversible dissolution of the mineral and is enhanced under acidic conditions.^[6,7] The release of interlayer K from micaceous minerals can

Fig. 2 The various sites of exchangeable K ions in micaceous clay minerals and the transition between mica and vermiculite layer that occurs when interlayer K is exchanged by hydrated, divalent cations.

proceed similarly or involve an ion exchange process (Fig. 1) leading to an expansion of the phyllosilicate (Fig. 2). This reversible release is essentially governed by the concentrations of K and competing cations in the outer solution.^[8,10,11] Cations that can be responsible for this release, such as Ca and Mg ions, have a large hydration energy, contrary to K or NH_4 ions. Therefore, they remain hydrated when exchanging interlayer K ions and expand the interlayer space (Fig. 2), making it possible for the release to proceed further, whereas NH_4 ions would block the reaction.^[12] However, because of the considerable affinity of these interlayer sites for K relative to Ca or Mg, the release can occur only for extremely low concentrations of K in the soil solution (Fig. 3), in the micromolar range.^[11,12] Conversely, elevated concentrations of K are prone to the reverse reaction of fixation, i.e., the collapse of expanded layers and concomitant increase in non-exchangeable K at the expense of readily available K. As long as exchangeable K was assumed to be the only plant-available K fraction, i.e., the poor recovery of applied K in the exchangeable fraction was seen as a poor efficiency of K fertilization. This apparent loss of applied K has therefore received considerably more interest than the reverse release process.^[7] In addition, the release of non-exchangeable K was considered unlikely to occur to any great extent, especially because K concentration in the bulk soil solution of fertilized soils is usually far above the critical concentrations that are prone to K release. However, numerous long-term fertilizer trials have shown that the release of non-exchangeable K contributes a major proportion of soil K supply in unfertilized and possibly fertilized plots too, although an overall net fixation is often found in the latter (Fig. 4).^[5,13] Non-exchangeable K can contribute up to $100 \text{ kg ha}^{-1} \text{ yr}^{-1}$, 80–100% of soil K supply. Such annual fluxes of release are fairly large compared with K dissolution rates commonly estimated by geochemists (in the order

of 5–15 kg ha⁻¹ yr⁻¹). However, many geochemical models do not take into account the amount of K taken off in the vegetation, leading to large underestimates of the actual dissolution rates.^[14] Conversely, many K budgets provided by agronomists do not take into account atmospheric inputs and leaching of soil K, assuming that these terms are fairly negligible in most cases. This certainly holds true for atmospheric inputs that rarely exceed values in the order of a few kilogram per hectare per year. Leaching can, however, vary over a much wider range of values from several kilogram per hectare per year in most cases up to several tens (and up to 1–3 hundreds) of kilogram per hectare per year in those situations that are the most prone to leaching: bare soil or poor soil coverage by the vegetation, excessive fertilizer rates, and coarse-textured soils. Omitting the leaching term would, however, have led to underestimating the actual release rate.^[5] Hence, considerable amounts of non-exchangeable K can be released in agricultural soils and contribute a significant proportion of plant uptake, in contradiction to the widespread viewpoint shared by numerous agronomists and soil scientists. Reasons for this can be found when considering root–soil interactions occurring in the rhizosphere.

POTASSIUM IN PLANT–SOIL INTERACTIONS

K occurs at rather low concentrations in the soil solution, compared to other nutrient cations and to the large

requirements of plants for K. The transfer of soil K via mass-flow toward plant roots (i.e., the convective flow of solute accompanying transpiration-driven water flow) contributes about 1–20% of plant demand.^[3,15–17] A direct consequence is the rapid depletion of K ions from the soil solution in the vicinity of plant roots, i.e., the rhizosphere. The resulting concentration gradient generates a diffusion of K ions in the rhizosphere, which plays a key role in the transport of K toward plant root (i.e., 80–99% of plant demand). Such depletion results in a shift of the cation exchange equilibria, which rule the dynamics of both exchangeable and interlayer K. This ultimately results in a desorption of exchangeable K and eventually of interlayer K,^[7,16,17] as shown by their depletion in the rhizosphere (Fig. 5). The extent of the depletion of exchangeable K will depend on chemical parameters such as the initial level of exchangeable K and the K buffering capacity of the soil and on physical parameters that directly determine the diffusive transport of K ions: soil texture and structure and soil water content.^[17] The K depletion zone will extend over several millimeters in clayey, dry soils up to several centimeters in wet, sandy soils.^[7,16,17] The intensity of the depletion will also depend on how far the K concentration of solution is decreased, which may vary among plant species according to the K uptake ability of their root. Plants with a lower external K efficiency, i.e., with a higher affinity transport system, will have the capability to take up K at lower K concentrations and may thus deplete soil K further.^[17] In the vicinity of roots, solution K concentration can indeed decrease by 2–3 orders of magnitude, down to as little as 2–3 μM .^[16]

Fig. 5 Depletion of both exchangeable K (gray dots) and HCl-extractable K (black dots) as a function of the distance from rape roots.

Source: Adapted from Jungk & Claassen.^[17] ©1997.

At such low K concentrations, the release of non-exchangeable K can occur at large rates, whereas it would be dramatically restricted at bulk soil K concentrations of several hundreds of micrometer (Fig. 3).^[11] Plants thus play a major role in the dynamic of inter-layer K via the root-induced depletion of solution K.^[16] Measurements in pot experiments have indeed revealed that within several days of growth, the release of non-exchangeable K can amount up to 90% of K supplied to the plant.^[7,16] Soil-root chemical interactions in the rhizosphere thus largely explain the unexpectedly large contribution of the release of non-exchangeable K to plant uptake that is found in many agricultural soils, including fertilized soils.

ASSESSING AND MANAGING POTASSIUM FERTILITY

Soil K fertility is most often evaluated by measuring exchangeable K^[1,7] most frequently with molar NH₄ acetate in batch conditions. However, the adequacy of exchangeable K to predict plant response, i.e., the actual bioavailability of soil K, is rather poor in many soils. This arises from the major contribution of the release of non-exchangeable K in some soils, especially when exchangeable K is low and/or when large reserves of non-exchangeable K are readily available as a consequence of: 1) soil mineralogical composition or 2) fertilization history (build up of fixed K due to excessive K-fertilizer rates). In these situations, quantitative evaluation of the potential release of non-exchangeable K would be highly recommended for a better prediction of plant response and fertilizer needs.^[7] There are several methods for assessing non-exchangeable K but none of them is routinely used on a broad scale because of their cost. These are either based on the use of 1) concentrated, strong acids that dissolve K-bearing minerals or 2) cationic resins or chemicals such as Na tetraphenylboron that can promote the release of interlayer K by removing K ions from soil solution and by shifting the exchange equilibria.^[6,7] Alternatively, correction factors can be used when interpreting exchangeable K values, which account either for the cationic exchange capacity (or clay content) or for the soil type and K release potential.^[7] Exchangeable K is nonetheless often used alone for fertilizer recommendations, resulting in frequently overestimated fertilizer needs to compensate for the expected large fixation and negligible release. Many long-term fertilizer trials have shown that adequate yields of crops can be obtained at fairly low rates of K fertilizer application, or even, for the least demanding crops such as cereals, without any K fertilizer for several years or decades.^[7,13] Other more demanding crops, however, require the application of K fertilizer to achieve high yield and quality in the harvested

products.^[18] The need for K fertilizers will thus depend on the release potential of the soil and on the demand of the plant, the latter being increasingly accounted for in fertilizer recommendations. Fertilizer trials have also shown that commonly used soluble K fertilizers and organic sources such as manure or crop residues have fairly comparable efficiencies. This is not surprising as K is highly mobile in organic compounds where it occurs as soluble or exchangeable K ions. These sources are thus equally important as K fertilizers and absolutely need to be accounted for in K budgets.

CONCLUSION

K is the major nutrient cation for plants and thus taken up at large rates by plant roots. These are achieved by both high and low affinity transport systems, which explain the considerable mobility of K within the plant. In comparison, K is much less mobile in soils because of the strong affinity of some exchange sites of clays. The large K uptake rates achieved by roots result in a steep depletion of solution K in the rhizosphere, and hence in a shift of the equilibria of cation exchange. Exchangeable K and even non-exchangeable K can thereby be significantly depleted and contribute a substantial proportion of plant uptake. This is confirmed by K balance in both short-term pot experiments and long-term field trials. In addition to the desorption-adsorption of exchangeable K, release and fixation processes thus need to be accounted for when evaluating soil K fertility.

Potassium: Dynamics and Mineralogy

A.V. Shanwal

S.S. Dahiya

Chaudhary Charan Singh Haryana Agricultural University, Hisar, India

Abstract

Potassium (K) exists in different forms, which are interrelated and maintain equilibrium in the soil system. The existence of these various forms of soil K and its incessant transformation from one form into another as well as the gain and losses generate a dynamic system in soil. The most important component of this dynamics is soil mineralogy, including primary and secondary minerals. The status of different forms of K in soil, their release characteristics, fixation, etc. are the other important components of K dynamics, which in turn are regulated by the soil mineralogical makeup.

INTRODUCTION

Soil contains some reserves of nutrients required by plants, which maintain the natural vegetation and food crops, the growth of which is regulated by the amount available. The natural reserve of potassium (K), a major essential plant nutrient, is fairly rich in soil. It comprises an average of 2.6% of the earth's crust, making it the seventh most abundant element and the fourth most abundant mineral nutrient in the lithosphere.^[1] K is the largest cation in non-hydrated state among the plant nutrients with 1.33-Å radius and 8–12 coordination number. K is generally preferred in ion-exchange reaction due to its higher polarizability (0.88 Å^3) and causes negligible swelling because of low hydration energy ($142.5 \text{ kJ g}^{-1} \text{ ion}^{-1}$) compared to other elements.^[2]

K occurs most frequently in the mineral, which is crystallized latest in the lithosphere and thereby concentrated in the earth's outer crust. The origin of K in natural soil resides in these K-bearing minerals, which release this element upon weathering during the soil-forming processes. Varying contents of K (0.4–3.0%) are thus found in the mineral soils depending upon the kind of K-bearing minerals, their degree of weathering, and the intensity of soil-forming processes. Most K in tropical and subtropical regions has been leached out of the soil profile because of strong weathering condition.

K MINERALOGY

K is an important constituent of layer and tecto aluminosilicates of primary and secondary minerals. The primary layer aluminosilicates include dioctahedral micas (muscovite

and glauconite) and trioctahedral micas (biotite and phlopopite). The tecto aluminosilicates are mainly K-feldspar, sanidine, orthoclase, and microcline feldspars. The secondary minerals include illite, transitional or interstratified clay minerals, and allophanes. Primary minerals contain 10% K. Among secondary minerals, illite contains a sufficient amount of K (3–8%), whereas transitional clay minerals and allophanes contain less than 1%.

Feldspars, Their Structure and Weathering

Feldspars are abundant in the igneous, sedimentary, and metamorphic rocks and constitute about 15% of the total lithosphere. Therefore, it forms a most important group of minerals and has made a special place in the classification from geochemical point of view.

The structure of K-feldspars is a 3-D framework of [silicon (Si) and aluminum (Al)]-O₄ tetrahedral groups by sharing of corner oxygen as in the case of SiO₂ polymorphs. The framework of four-membered rings of tetrahedral groups encloses large interstices occupied by K, sodium (Na), calcium, barium, and other cations. In sanidine, orthoclase, and microcline, these sites are occupied by K. The K–O distances ($\sim 3 \text{ Å}$) indicate an irregular nine-fold coordination for the K⁺ ion. The polymorphism of K-feldspars (sanidine, orthoclase, microcline, and adularia) has an ideal chemical composition of KAlSi₃O₈, where one out of every four Si atoms in the framework is replaced by Al. In nature, it hardly occurs but contains foreign cations either by replacing Si or Al in four-fold coordination or by K⁺ ions in 8–12-fold coordination.^[3]

The exact mechanism of feldspar weathering is not very clear. Proteolysis is probably the most important reaction

resulting in the release of K from feldspar. Depending upon the amount of H_3O^+ ion, the hydrolysis of feldspar takes place as shown in Eqs. 1–3.

In the presence of excess hydronium ion, at low pH, total hydrolysis releases K^+ and solubilizes the silica and reprecipitates Al as $\text{Al}(\text{OH})_3$. Medium hydronium ions transform the feldspar into kaolinite through partial hydrolysis at low pH. However, the partial hydrolysis also produces smectites (montmorillonite and beidellite) but at alkaline pH and poor drainage condition.^[4]

Unlike mica, the weathering of feldspar proceeds through surface reactions in which K^+ is replaced by H_3O^+ . The K^+ ion diffusion slows down with time due to the development of thin (30-nm) residual layer of amorphous material around the feldspar grains. Apart from the weathering environment, the structural properties of the feldspars affect the weathering rate including its composition, Na content, the order of Si and Al in the crystal structure, crystal and particle size, purity, and nature of the twinning. Based on the degree of disorder of the Al and Si distribution in K-bearing feldspar, the weathering sequence follows as: sanidine > orthoclase > intermediate microcline and maximum microcline. In perthitic structures, albite is more weatherable than the K-feldspars due to the presence of Na^+ ion. Among feldspars, maximum microcline is most resistant to weathering due to Si/Al order, low Na content, lack of perthitic structure, and crystal size.

Micaceous Minerals: Their Structure and Weathering

Micaceous minerals in the soil and rocks include primary mica (muscovite, biotite, and phlogopite), hydrous mica or degraded mica, and illite. Micas are third most extensive group of minerals after feldspars and quartz in igneous and metamorphic rocks.

Structurally all the micaceous minerals are similar and belong to group 2:1 phyllosilicates of the silicate mineral class but differs in K content. Primary mica contains 10% of K while hydrous micas and illites contain only 3–5%. The structural unit of mica consists of one layer of Al^{3+} octahedra sandwiched between two layers of Si^{4+} tetrahedra. Similar to feldspars, every fourth Si^{4+} tetrahedron is replaced by Al^{3+} creating a unit negative charge per four tetrahedra. Finally, when each such layer is joined face to face with another, the residual charge is neutralized

by K^+ fitted in the 12 coordinated hexagonal holes. But, K^+ is 6 rather than 12 coordinated because in each hexagonal holes three alternate oxygen move inwards and remaining three move outwards and are at a distance of 2.81–3.40 Å from K ions.^[5]

In the trioctahedral micas, the central cation is divalent (Mg^{2+} or Fe^{2+}) and all the three octahedral positions are filled, whereas in dioctahedral micas, the central cation is trivalent (Al^{3+} or Fe^{3+}) and only two out of three octahedral cation positions are filled. The stylized mica structure corresponds to a unit cell with approximate dimensions: $a = 5$ Å, $b = 9$ Å, $c = 10$ Å, which is monoclinic with $\beta = 95^\circ$. This unit cell chemical formula is $\text{K}_2\text{Al}_4(\text{Si}_6\text{Al}_2)\text{O}_{20}(\text{OH})_4$ for dioctahedral and $\text{K}_2\text{Mg}_6(\text{Si}_6\text{Al}_2)\text{O}_{20}(\text{OH})_4$ for trioctahedral.

Approximately 95% of the clay minerals of soils are produced by weathering of micas. The transformation of micaceous clay begins at a particle size of <0.2 μm. Although the weathering of mica involves proteolytic reaction, unlike feldspars, the H_3O^+ ions attack the lateral edges of the particle and proceed zonally inward toward the center of the mica lattice. During this process, the edges expand to ~18 Å by releasing K^+ ion and reducing the layer charge. The expansion of interlattice space of mica and release of K^+ ion and reduction in layer charge eventually result in a series of mineral transformations as follows:

This series of mica transformation ends with swelling clay minerals such as smectite and vermiculite (Fig. 1) in neutral or alkaline pH soils, but in acidic soils the release of K^+ ion from micas proceeds with the dissolution of the mineral followed by the formation of weathering products including kaolin and hydroxides of iron and aluminum.^[6]

However, the weathering of mica is mainly governed by the amount of H_3O^+ ion in the soil environment although structural characteristics of the mineral such as tetrahedral rotation and tilting, hydroxyl ion orientation, octahedral cations, particle size, and K depletion also play an important role. The weathering of the trioctahedral mica (biotite and phlogopite) is much more rapid than the dioctahedral mica (muscovite) due to its structural imperfection.

Transitional Clay Minerals and Allophanes

Although K is not part of the structure of these minerals and its content is also much less (~1%), they play an important role in plant nutrition through cation-exchange reaction. Transitional or interstratified clay minerals are the intermediate stage of mica transformation in which some or more

Fig. 1 Optical and electron micrographs of various stages of mica transformation in southern Haryana soils: (A) fresh biotite mineral without exfoliation and wrinkles; (B) weathered biotite showing fissures and crevices; (C) biotite particles transformed into interstratified minerals; and (D) biotite completely transformed into smectites.

layers of mica gets transformed into swelling minerals (smectite or vermiculite) either in regular, irregular, or random fashion.

Allophanes are series of hydrous aluminosilicate minerals of widely varying composition. Allophane has a definite affinity for K because of its structural configuration and has high CEC.

SOIL K DYNAMICS

Plant absorbs K from soil solution but its amount is so low that plant cannot complete its life cycle merely on this basis and is replenished from the reserve pool. As a result, K maintains equilibrium between its various phases referred to as K dynamics (Fig. 2).

Sharp distinction between various phases of K is not possible and often there is an overlap between these forms due to their dynamic equilibrium. The available K (solution K + exchangeable K) usually forms a small fraction (~2%) of the total K but is often large enough to satisfy plant requirements of short duration crop, although too small to be able to meet the needs of one large duration crop or several short duration crops. Therefore, for sustainable crop production, the available K must be continually replenished through non-exchangeable and mineral K reserves.

The dynamic equilibrium between solution, exchangeable, non-exchangeable, and mineral forms of K strongly influences K chemistry. The rate and direction of these reactions determine the release, fixation, plant uptake, and leaching of applied and native K. The kinetics of reactions

between these phases is prerequisite for making proper recommendations for K fertilizer use.

Kinetics of K Release

The release of reserve K is actually not the result of dissolution of K-bearing minerals but is an exchange reaction, which is so slow that it cannot be measured with normal methods of determining exchangeable K. During the course of plant growing season, K in soil solution is continually being replenished through release from exchangeable form, which in turn is replenished from non-exchangeable and mineral K.^[7]

Various methods and extractants such as salts, ion-exchange resins, sodium tetraphenyl boron (NaTPB), and organic and mineral acids have been used to study the kinetics of K release from the soil and its different fractions.^[8]

Normally nitric acid (HNO_3) extracts the highest amount of non-exchangeable K from soils followed by H-resin, NaTPB, and oxalic and citric acids. A number of

Fig. 2 The dynamics between various forms of K.

Fig. 3 Kinetics of non-exchangeable K release from the soils of North India to hydrogen region as described by elovich equation.

equations have been used to describe K^+ release kinetics in soils. These include the zero-order, first-order, elovich, and parabolic diffusion equations.^[9] The first-order equation is most successful to describe K kinetic release and K uptake by plants by most methods except H^+ resin, which obeys elovich equation with curvilinear pattern (Fig. 3).

The release of K is directly governed by the amount and mineralogical composition of soils. The illitic soils show the highest rate of K release followed by smectitic and kaolinitic soils regardless of the content of exchangeable K in the soils. The high rate of K release at the initial stage is mainly due to external domain (surface and edges) and the slower rate due to the restricted domain (interlayer sites) through diffusion.

K Fixation

Fixation of K is conversion of soil solution or exchangeable K into non-exchangeable forms. Normally the fixation and release of K occur simultaneously. In soils containing predominantly micaceous and vermiculite minerals, a large fraction of added K can be fixed. The fixation may convert the swelling clay minerals into micaceous minerals. The swelling clay minerals (14 Å) when dried in the presence of K ions lose their shell of water molecule and allow K ions to enter the pseudohexagonal space between tetrahedral layers and become electrostatically bound.^[10]

SOIL TEST CROP RESPONSE OF K

Various extractants and methods have been used for assessing the portion of soil K that is available to plants.^[11] Probably most widespread is the use of neutral 1 M NH_4OAc solution. Other extractants frequently used are Bray solution, various salts, buffered or unbuffered NH_4 -oxalate, double acid ($HCl-H_2SO_4$), Morgan's extract, dilute H_2SO_4 , organic acids, NaTPB, HNO_3 , etc.^[10]

Backett's quantity and intensity relationship (Q/I) and electro ultra filtration (EUF) at various potentials are also methods for estimating the available K but are not in common use due to the cost-effective and cumbersome nature.

Soil tests for K are used as bases for fertilizer recommendations for crops. Therefore, any method that samples the available fraction of plant nutrient can be used as a satisfactory soil test, and hence as a basis for making fertilizer recommendations provided a calibration curve relating soil test vs. yields through the normal response range is available.

Normally a very high correlation coefficient is observed between K extracted by neutral 1 M NH_4OAc and K uptake by plants and plant yields. However, this method fails in light textured soils of arid and semiarid regions where exchangeable K content is almost negligible. Under such conditions, 0.5 M HNO_3 , NaTPB, and EUF are more reliable methods in estimating the K available to plants as they also extract non-exchangeable K. The long duration crops also extract non-exchangeable K particularly in light textured soils under stress condition.^[9,12]

CONCLUSION

K is an important constituent of feldspars and micas, which weather and release K through proteolytic reaction but by different mechanisms. The weathering of feldspars proceeds through surface reactions and is a function of soil environment (pH, Eh, etc.) and its structural imperfection. Microcline feldspar is most resistant to weathering due to Si/Al order, lack of perthitic structure, and crystal size. Unlike feldspars, micas weather through interlattice expansion. Trioctahedral micas weather faster than dioctahedral micas due to shorter bond length and greater bond strength of K-O in the latter. Transitional clay minerals contain a negligible amount (~1%) of K but play an important role in plant nutrition.

K exists in different forms, which are in dynamic equilibrium. The rate and direction of these equilibria determine the release, fixation, plant uptake, and leaching of applied and native K. The kinetics of K release by most methods is explained by first order equation. Illitic soils release the highest K followed by smectitic and kaolinitic soils. The swelling clay minerals (smectite and vermiculite) fix appreciable amounts of added K.

Soil tests for K are used as basis for fertilizer recommendations for crops. Neutral 1 M NH_4OAc method is widely used for assessing available K. However, inclusion of non-exchangeable K is also relevant.

Potassium: Nutrition in Semi-Arid Tropics

D.L. Oswalt

(Retired), Plymouth, Michigan, U.S.A.

Abstract

Short periods of intense rainfall causing waterlogging in warm Alfisol or Vertisol topsoils apparently reduce the uptake of potassium (K) ions from the active root zone. Highest grain yields, comparing 13 years of data in the semiarid tropics, unexpectedly occurred during the years with adequate but lower rainfall. K deficiency symptoms may appear prior to nitrogen or drought symptoms as rainfall diminishes. Midseason soil tests indicated reduced available K, as sample depth was increased. Sorghum embryo number may be reduced owing to inadequate nutrients being transported to the fertilized cells, resulting in lower grain yield when the topsoil becomes waterlogged at flowering time. Muriate of potash or potassium chloride applied to soils in the semiarid tropics, where salts are not normally leached through the soil profile, may not show a positive response in plant growth.

INTRODUCTION

Personal observations in northeastern Nigeria found small spots of well-developed grain sorghum [*Sorghum bicolor* (L.) Moench] in farmer's fields where grass or brush heaps had been burned, where wood ashes were present in the soil around compounds, on old termite mounds, and in drip areas of certain trees with leaves high in nitrogen (N) and potassium (K). Farmers often grow vegetables on raised beds or ridges in semiarid regions. These observations indicate that added K improves plant growth. Dry season soil tests of Alfisols and Vertisols often indicated adequate available K for normal plant growth; however, grain yields are low.

DEMONSTRATIONS

Vegetative growth of rain-fed grain sorghum and other crops in the semiarid regions with basal applications of fertilizer often appears normal prior to flowering (personal observations); however, grain yields are seldom 50% of the same variety grown in temperate regions. Personal observations found general yellowing of the older leaves occurring soon after flowering where topsoils had been waterlogged during high rainfall events. Plant tissue tests^[1] conducted on such plants indicated that N and P were present and K was very low in the leaf or stem sap. Soon after rainfall ceased, the lower leaves yellowed from N deficiency and drought resulted in brown lower leaves.

Long-term muriate of potash trials in Nigeria and potash fertilizer trials in India all indicated no benefit, and in some incidents, there was no plant growth at the higher applications of muriate of potash. Semiarid tropical soils often form salt deposits on the surface due to poor drainage or lack of normal leaching of salts through the profile.^[2] This

poses the question of potential toxicity to the chlorine ion^[3] from muriate of potash. Personal demonstrations using potassium chloride, potassium nitrate, and ammonium nitrate applied to sorghum at flowering produced a noticeable yield increase only from the potassium nitrate.

Two hybrid grain sorghum varieties were used as checks during 13 years of replicated yield trials by the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) trainees. Of the highest yielding experiments, 8 or 10 were selected from each year's trials. These average grain yields were compared with rainfall data. Unexpectedly, the lowest grain yields were produced in years when rainfall during June, July, and August exceeded 600 mm (Fig. 1). These sorghum hybrids indicated little variation in seed weight from year to year. Therefore, grain yield differences were due to variations in seed number. These results were not predicted for the semiarid tropics where rainfall is considered as yield-limiting. It has been reported that depleted oxygen supply and repeated wetting and drying constrain normal water and nutrient uptake.^[3–6] This would indicate that saturation of the soil in midseason limits grain yield. (See also the entry *Aeration: Tillage Effects*, p. 47.)

Personal tests of the sorghum leaf tissue from a yield trial on a Vertisol (when it was very difficult to walk through the wet plots) indicated high levels of N and P and a low level of K at the time of initial flowering. In replicated plots, Hoagland's solution was applied in the row between plants through tubes to a depth of 15–20 cm. In adjacent plots, Hoagland's solution minus K was applied to maintain the same application of water and other nutrients. Eight sorghum plants at 50% flowering and with similar plant heights (similar physiological development) were tagged on the same date in all plots. A few days later, the plant sap indicated a lower level of K, but higher levels of

Fig. 1 Hybrid grain sorghum grain yield compared to rainfall (10 kg/ha or mm).

N and P in the plots receiving Hoagland's solution minus K. Plant sap from the plots receiving the complete Hoagland's solution indicated high levels of N, P, and K. Subsequent grain yields indicate a 30% increased grain weight where complete Hoagland's solution had been applied (Table 1). The similar seed weight indicates an increased number of embryos survived and matured where the complete Hoagland's solution was applied. Therefore, the roots remained active;^[3] however, they were not taking K from the soil after the topsoil had been wet from intense rainfall events.^[3,7]

Moist Vertisol soil samples (corrected for moisture content) collected from a fallow crop rotation plot during 1992 and their dried samples were tested for ammonium acetate-extractable K (mg kg^{-1}). Apparent soluble K was lower in all samples than that in dry soil samples taken during the previous dry season.^[3] The extractable K was lower at greater depths and in the moist samples before drying (Table 2), indicating that the available K had not leached downward. The 1992 annual rainfall was among the lower years (Fig. 1).

CONCLUSIONS

Demonstrations and observations indicate a midseason reduction of K uptake from soils (normally testing high in available K in the semiarid tropics where soil organic matter is usually low) that unexpectedly reduces sorghum grain yield during years with more than 600 mm rainfall during June, July, and August. Factors reducing the uptake of K from temporarily waterlogged root zones, caused by intense rainfall, merit the identification of the systems and time involved. The identification of effective topsoil drain-

Abstract

An option that has been proposed to combat the buildup of greenhouse gases in the atmosphere is the capture of carbon dioxide (CO₂) at a power plant and injection of CO₂ into a geologic formation for permanent storage, a process generally referred to as carbon capture and storage. However, because CO₂ in power plant flue gas is at a low partial pressure, the technology for CO₂ capture is expensive and could raise the cost of power by 50–100% for new pulverized coal plants, with considerably higher increases possible for plants retrofitted with CO₂ capture systems, when the cost of replacement power is included. This entry describes the processes for CO₂ capture and some new technologies that hold promise of increasing efficiency and reducing costs.

INTRODUCTION

There is a growing concern that the buildup of carbon dioxide (CO₂) in the atmosphere is contributing to global climate change. The combustion of fossil fuels, particularly coal, in power plants for the production of electricity is a major source of CO₂ emissions. A promising approach to reducing greenhouse gas emissions from fossil-fuel-fired power plants and other large point sources is carbon capture and storage (CCS), which involves the capture of CO₂ from a large point source, transport to a storage site, and injection into a geologic formation for essentially permanent storage. The first, and most expensive, step in this chain is CO₂ capture.

CO₂ CAPTURE

There are three basic schemes for the capture of CO₂ from fossil-fuel-fired power plants ([Fig. 1](#)): postcombustion capture, precombustion capture, and oxygen-combustion (oxy-combustion). In postcombustion capture, CO₂ is recovered from the flue gas produced when the fuel is burned. In precombustion capture, the fuel is decarbonized before combustion, and in oxy-combustion, the fuel is burned in an oxygen-enriched environment using pure oxygen

diluted with recycled flue gas or steam to produce a flue gas consisting predominantly of CO₂ and water vapor (H₂O), from which CO₂ is recovered by condensing the water. The advantages and disadvantages of these three options are summarized in [Table 1](#).

POSTCOMBUSTION CAPTURE

Most fossil-fuel-fired power plants use air as the oxidant. The result is that the flue gas produced contains a large amount of nitrogen (typically about 70% for a coal-fired plant) with CO₂ concentration being in the range of 13–15%. Since flue gas is typically at about atmospheric pressure, the driving force (CO₂ partial pressure) for CO₂ capture is very low.

Because CO₂ removal from streams, such as natural gas and hydrogen (H₂), is important in the oil and gas industries, a number of processes have been commercialized for recovering CO₂ from gas streams. These processes break down into two categories: those based on physical solvents, in which the CO₂ merely dissolves in the solvent like CO₂ in seltzer water, and those based on chemical solvents, in which a weak chemical reaction occurs between the CO₂ and the solvent. The capacity of a physical solvent is a

Fig. 1 Schematic diagram showing carbon capture options.

Source: From Figueroa, Fout, et al.^[1]

function of the partial pressure of CO₂. Physical solvents are regenerated by reducing pressure, increasing temperature, or both. Because of the low CO₂ partial pressure in flue gas, physical solvent-based processes are not feasible for postcombustion CO₂ capture.

Since chemical solvents act through a different mechanism (forming a weak chemical compound with the CO₂), they can absorb CO₂ even when the CO₂ has a very low

partial pressure. The solvent is regenerated by heating, which breaks the chemical bond and releases the absorbed CO₂. Most of these processes are based on the use of an amine as solvent. Popular solvents are monoethanolamine and diethanolamine (DEA), although other amines are sometimes used. With DEA, the reaction can be represented by:

Table 1 Advantages and disadvantages of different CO₂ capture approaches.

	Advantages	Disadvantages
Postcombustion	Compatible with the state-of-the-art pulverized coal-fired boilers Could be retrofit to the majority of coal-fired power plants	Flue gas is diluted in CO₂ and at ambient pressure Low CO₂ partial pressure requires use of a chemical solvent for a high capture level CO₂ recovery at low pressure requires a large compressor load The above factors result in a significant decrease in plant efficiency and output
Precombustion	Synthesis gas is at high pressure and has a high CO₂ concentration High CO₂ partial pressure results in a large driving force for CO₂ capture Able to use physical solvents for acid gas capture Recovery of CO₂ at higher pressure results in reduced compression costs	Applicable mainly to new plants, as few gasifier-based plants are currently in operation Gasifier-based power plants are not cost competitive, which limits the applicability of precombustion CO₂ capture
Oxy-combustion	Very high CO₂ concentration in flue gas Possibility exists to retrofit and repower plants	Large cryogenic O₂ production requirement Cooled CO₂ recycle required to maintain temperatures within limits of materials in furnace Need for oxygen plant and CO₂ recycle increases auxiliary power load and decreases plant efficiency

Processes have also been developed that use a potassium carbonate (K₂CO₃) solution, such as UOP's Benfield™ process. Carbonate-based systems work by the conversion of carbonate to bicarbonate in the presence of CO₂, followed by the conversion back to carbonate by heating with release of the absorbed CO₂, as indicated by the following reaction:

A major advantage of carbonate systems over amine-based systems is the significantly lower energy required for regeneration. Additives are sometimes included to improve absorption rate or provide other benefits.

In contrast to physical solvents, the capacity of a chemical solvent does not depend strongly on CO₂ partial pressure. Rather, it depends mainly on the concentration of the sorbent and the completeness of regeneration. Amine solvents are typically limited to concentrations of about 30% because of corrosion problems at higher concentrations. Another problem with chemical solvents is that they can form stable compounds with impurities in the flue gas and, thus, gradually lose their effectiveness. There is also a certain amount of degradation that occurs from oxygen in the flue gas. Furthermore, amine-based units have yet to be built at the scale necessary to scrub CO₂ from the flue gas of a large power plant. Some cost reductions are expected from continuing work to increase capacity and stability and reduce energy requirements.

PRECOMBUSTION CAPTURE

In precombustion capture, the fuel is decarbonized before it is burned. This typically involves gasifying the fuel, usually coal, by contacting it with a mixture of oxygen and steam to form synthesis gas (referred to as syngas), a mixture of H₂ and carbon monoxide (CO), along with smaller amounts of other gases, such as H₂O, CO₂, hydrogen sulfide (H₂S), ammonia (NH₃), and methane (CH₄). Gasification is the first step in a power-producing process known as integrated gasification combined cycle (IGCC), as shown schematically in the second row of Fig. 1. The syngas is subjected to the water–gas shift (WGS) reaction to convert CO into CO₂ plus H₂. Typical reactions occurring are as follows:

Other reactions also occur, but the above mentioned are the most important. After CO₂ removal, the H₂ is burned as a fuel in a combustion turbine and produces only H₂O. Since H₂ has different properties than CH₄ or CO, the combustion turbine must be redesigned to burn a high H₂ content fuel.

There are several advantages to this approach. First, gasifiers can operate at moderate pressures (500–1000 pound/in.²). This permits the use of physical solvents for CO₂ capture, rather than the more expensive chemical solvents. The most popular acid gas removal processes based on physical solvents are Rectisol[®], which uses methanol as a solvent, and Selexol[™], which uses a mixture of dimethyl ethers of polyethylene glycol. Second, because the gasifier runs at reducing conditions (as opposed to oxidizing conditions in a furnace), sulfur in the fuel is converted to H₂S rather than SO_x, and the nitrogen in the fuel is converted to NH₃ rather than NO_x. H₂S can be removed by the same physical solvent used for CO₂ removal, using a two-stage process, and converted to elemental sulfur, a saleable product. NH₃ can be scrubbed out with a water wash. Thus, with these systems, it is easier to remove sulfur and nitrogen in the form of H₂S and NH₃ than with systems requiring the removal of SO_x and NO_x. The biggest disadvantage of IGCC is that an oxygen plant is required, which significantly increases costs.

OXY-COMBUSTION

Oxy-combustion involves burning the fuel in an oxygen-enriched environment, where pure oxygen is diluted with recycled flue gas or steam so that the flue gas is almost entirely CO₂ and H₂O. When the H₂O is condensed, a nearly pure CO₂ stream is left. Depending on specifications and regulations, it may be necessary to remove trace contaminants, such as SO_x and NO_x, from the CO₂ before it can be injected into a pipeline for transport to a site for enhanced oil recovery or storage in a geologic formation. If CO₂ cleanup is required, costs for the oxy-combustion option will be somewhat increased.

Because combustion in pure oxygen would result in much higher furnace temperatures than that can be tolerated by materials of construction, flue gas recycle is necessary, which increases costs. Another disadvantage of oxy-combustion is the requirement for an oxygen plant. In the precombustion option, only part of the fuel is burned in pure oxygen, but in oxy-combustion, all the fuel is burned in pure oxygen, so a larger oxygen plant is needed. Oxy-combustion has the potential for higher efficiency, when compared to air-fired combustion, if boiler materials that can withstand higher temperatures are developed.

EMERGING CAPTURE TECHNOLOGIES

If a new pulverized coal power plant were built incorporating the state-of-the-art CO₂ capture technology, the cost per tonne of CO₂ avoided would be about \$75, and the cost of electricity would increase by over 80%, with considerably higher increases possible for plants retrofitted with CO₂ capture systems, when the cost of replacement power is included. CO₂ capture is by far the most expensive step in CCS, accounting for about 75% of the cost. Therefore, for large-scale implementation of CCS to be practical, more cost-effective CO₂ capture technology is needed. Fig. 2 depicts some of the emerging technologies and the approximate time frame when they may be available. Some of these technologies are discussed below.

Aqueous NH₃

NH₃-based systems behave similarly to amine-based systems, but have several advantages, including significantly lower heat of regeneration, higher CO₂ capacity, lack of

Fig. 2 Schematic diagram showing cost reduction benefits of innovative CO₂ capture technologies versus time to commercialization. ITM, ion transport membrane; CAR, ceramic autothermal recovery; OTM, oxygen transport membrane.

Source: From Figueroa, Fout, et al.^[1]

degradation during absorption/regeneration, and low cost. The chemical reaction is as follows:

There is also a potential for the simultaneous absorption of SO_x and NO_x to form ammonium sulfate and ammonium nitrate, which can be sold as fertilizer.

A major concern with NH_3 is its high volatility. This may require cooling the flue gas to the temperature range of 60–80°F to reduce NH_3 losses and then reheating it after CO_2 removal, which would increase costs.

Membranes

Another option under investigation is the use of various kinds of membranes to recover CO_2 . As a way of separating CO_2 from flue gas, membranes have the same problem as physical solvents—a low driving force (the difference in CO_2 partial pressure on the two sides of the membrane). Since the partial pressure of CO_2 in a typical flue gas is considerably below 1 atm, a vacuum is required on the permeate side. Compressing CO_2 from subatmospheric pressure to 2000 pound/in.² (a typical pressure for geologic storage) is expensive.

Because of the higher partial pressure of CO_2 , the use of membranes with precombustion capture may be more promising. Fig. 3 depicts the results from a polybenzimidazole (PBI) membrane under development at U.S. Department of Energy's Los Alamos National Laboratory. This membrane has shown hydrothermal stability up to 400°C and sulfur tolerance when operating on simulated coal-derived syngas, and its performance exceeds the Robeson upper bound for H_2/CO_2 selectivity versus permeability.

Fig. 3 Trade-off plot between H_2 permeability and H_2/CO_2 selectivity for polymers. The PBI membrane shows excellent performance.

Solid Sorbents

Solids can act as physical sorbents (e.g., molecular sieves) or form a chemical compound, which is regenerated by heat. Many CO_2 solid sorbent processes under development tend to mirror liquid sorbent processes by being either amine based or carbonate based. Amine-based systems use an amine that is stabilized by being absorbed on a porous substrate. After a CO_2 absorption cycle, the sorbent is heated to release absorbed CO_2 . A carbonate system being investigated is sodium carbonate, which reacts to form sodium bicarbonate. The bicarbonate is regenerated to carbonate by heating.

Solid-based systems are inherently more complex than liquid-based systems because solids are more difficult to handle. Two approaches are possible: 1) moving (or fluidized) beds for the solids and 2) fixed beds with periodic gas flow switching. Because of the large volume of flue gas from a typical coal-fired power plant, equipment sizes will be large in either case.

A novel solid sorbent being investigated is metal organic frameworks (MOFs). These MOFs are a new class of hybrid material built from metal ions with well-defined coordination geometry and organic bridging ligands. They are extended structures with carefully sized cavities that can adsorb CO_2 . High CO_2 capacity should be possible, and the energy required for regeneration is low.

Novel Liquid Sorbents

Novel liquids being investigated as potential sorbents for CO_2 include ionic liquids (ILs). ILs are a broad category of salts, typically containing an organic cation and either an inorganic or an organic anion. They can dissolve CO_2 and are stable at temperatures up to several hundred degrees centigrade, thus offering the possibility of being able to recover CO_2 from flue gas without having to cool it first. Since ILs are physical solvents, little heat is required for regeneration.

Chemical Looping

Chemical looping is a variant of oxy-combustion in which the oxygen is provided by an oxygen carrier, such as a metal oxide, rather than by an oxygen plant. The fuel is contacted by the metal oxide in a combustor, where the fuel is oxidized to produce a flue gas, which is predominantly CO_2 and H_2O , while the metal oxide is reduced. After reduction, the reduced metal is contacted with air to regenerate the oxide. This reaction is exothermic, and the hot nitrogen leaving the oxidation stage is used to raise steam for power production. CO_2 is recovered by condensing the water in the flue gas. A possible embodiment of the concept is to use two fluidized beds (similar to fluid catalytic cracking units used in petroleum refining), oxidation occurring in one vessel and reduction in the other. After heat recovery

to raise steam, the oxygen-depleted air is exhausted to the atmosphere. This approach is a way to practice oxy-combustion without requiring an oxygen plant.

Improved Auxiliary Processes

If power plants are required to reduce CO₂ emissions and CCS is adopted as a CO₂ mitigation strategy, it seems likely, for the reasons discussed earlier, that new plants will be based on IGCC or oxy-combustion technology. However, deployment of these technologies must overcome high capital costs that affect commercial competitiveness and the ability to raise capital. One way to improve efficiency and economics for IGCC and oxy-combustion is to develop improved auxiliaries, such as air separation and WGS technology. One possibility is the use of tubular membranes; e.g., tubes made of an oxygen transport membrane could be inserted into a furnace. When air is blown through the tubes, oxygen diffuses into the furnace and combusts the fuel, thus achieving oxy-combustion without the need for a cryogenic air separation unit.

Catalyst-filled membrane tubes could be used in a WGS reactor to remove one of the products (H₂ or CO₂) from the reaction, thus allowing complete reaction in one reactor, instead of requiring multiple reactors operating at successively lower temperatures.

Another area where improvements are possible is the compression of CO₂. Studies are underway to determine the most efficient compressor design for compressing CO₂ to about 2000 pound/in.^[2], including looking at Ramjet technology. The option of compression to an intermediate pressure, followed by liquefaction and pumping to 2000 pound/in.², is also being evaluated.

CONCLUSION

CCS is a promising technology for reducing CO₂ emissions from fossil-fuel-fired power plants. However, the state-of-the-art technology is expensive and significantly reduces plant efficiency. Furthermore, this technology has not been implemented at the scale necessary to treat the flue gas from a large power plant. Thus, if CCS is to have an impact on mitigating global climate change effects, improved capture and auxiliary processes will need to be developed. Further information on CO₂ capture is provided in the references.^[1,3–5]

Abstract

It seems possible that all agricultural operations could be monitored and recorded, linked by digital transmissions to databases containing weather, remote sensing, and historical data, and controlled through a general model of the crop's predicted response to specific inputs. Such a system may not only control specific agricultural operations but also be involved in scheduling, ordering seed, fertilizer, and supplies, providing records to regulating agencies, and feeding valuable information back into the research system for further refinement of the control model.

INTRODUCTION

Information technology is playing an increasingly important role in agricultural production systems of all sizes, commodities, and management philosophies. Precision agriculture^[1–3] or site-specific management is an information-based management technique that has the potential to improve profitability^[4] and reduce the environmental impact^[5] of crop production. It also has the potential to improve the quality and nutrient content of the product. Precision agriculture, rather than the “one-size-fits-all” management strategy, provides for differential treatment of selected areas of a production field, called management zones, based upon the expectation of increased yield, profit, or some other agronomic goal.^[6–9] Management zones may be selected for differential treatment based upon various documented differences such as soil type, soil fertility or pH, yield history, presence of weeds, insects, or diseases, or other measures for which a differential treatment helps the producer achieve a selected goal. The ability to provide differential treatment to management zones, also called site-specific management, depends upon the availability of both proper equipment and effective treatment algorithms.

WHAT MAKES IT POSSIBLE?

Precision agriculture techniques have been made possible by the advent of global positioning system (GPS) and high-speed computer processing. GPS provides real-time

location information to a computer that, from stored information, determines the management zone, selects appropriate treatment for that management zone, and controls mechanisms to provide the treatment. Fig. 1 is a graphic representation of the precision agriculture paradigm. GPS provides position information for a variety of data gathering processes or for the control of site-specific treatments. The information of various types (shown as layers) may be used in analysis of yield results or to develop an application map to control site-specific treatments. The whole system taken together is often called precision agriculture or site-specific agriculture. Note that a feedback loop is implied where results of the previous growing season (yield) become part of the information that influences the treatment practices. Given the proper treatment algorithms, the treatment practices may optimize the goal parameter. Maximum yield is not necessarily the best goal because the cost of treatments required to achieve that yield may be greater than the increased crop value.^[8,9]

GPS consists of a minimum of 24 satellites circulating around the earth sending signals to a local receiver for which location is desired.^[10] Each satellite broadcasts encoded information with particular timing. By measuring the time a signal travels (at the speed of light) to reach the receiver, the distance from a satellite to the receiver may be calculated. Determining distances from four or more satellites of known location may establish the receiver's location (latitude, longitude, and elevation). Even simple, inexpensive receivers are capable of accuracy better than 15 m, close enough to return to a favorite fishing spot. With

Fig. 1 Paradigm for precision agriculture.

specialized transmissions containing information to correct for known errors (called differential signals), accuracy better than 1 m may be achieved. Specialized local transmitters make possible real-time kinematic (RTK-GPS) systems with an accuracy of better than 1 cm. RTK systems are used in surveying and guidance, where the fine precision may justify a relatively high equipment cost.

High-speed computer processing systems have also played an important role in the advent of precision agriculture. Precision agriculture requires collection and storage of data, decision-making computation, and controlling of equipment by computers operating at billions of operations per second. GPS locations are recorded in real time by the computer. Digital maps of field conditions and parameters are carried in memory or storage media. Digital data such as digital still or video images of weeds, insects, or disease damage, soil properties, crop spectral reflectance, or climatic conditions may also be collected in real time by the computer. Using such information, the computer may work

through a response model to decide what actions should be taken with existing equipment. For example, a precision agriculture capable planter may be able to adjust planting rate and depth or change the seed variety on the go. Thus, the computer may decide that areas with a selected soil type and relative elevation will get a reduced population (investment of seeds) because less yield is expected. The computer may dictate that another soil type with a high yield potential and high existing moisture content will get a different variety planted to a shallower depth. Across an entire field, many combinations of the controlled variables will be chosen to optimize the desired result (yield, profit, or other goal). A large field would require constant decisions and adjustment of the equipment that would not be possible without computerized systems. Finally, volumes of data may be produced by precision agriculture techniques, and computer methods are being developed to extract useful information; models form these data^[11–16] and present them to the public in a readily accessible form.^[17]

SENSING FOR PRECISION AGRICULTURE

Real-time sensors will be important to many precision agriculture systems.^[18] A real-time sensor provides data in a nearly constant stream as the machine traverses the field. For example, a camera may provide digital images from which the presence of weeds may be determined. A sprayer may then be directed to spray only where weeds are present. Organic matter and moisture levels in soil affect the performance of some herbicides. Sensors that measure organic matter and/or moisture on the go allow for optimum rates of chemical application—adequate to control the weeds but no more than necessary to preserve environmental quality.

One of the most popular real-time sensors measures grain yield on combines.^[11] Yield sensors are also available or are being developed for a variety of crops such as cotton, potatoes, tree fruits, and strawberries. Yield sensors provide a measure of yield over a whole field. Areas of the field with unusually high or low yield may be identified, and corrective action (subject to some predictive model created by the producer or by computer) can be taken for the following year. This one aspect of precision agriculture has created a lot of activity in adjusting soil drainage and fertility and crop management decisions such as the relative value of fertilizer or chemical inputs.

For many agronomic parameters, site-specific soil sampling is more practical, either because a real-time sensor is not yet available or because the spatial variation of the parameter is more gradual and can be estimated with a few site samples. Soil samples to determine fertility are common. The values of pH (acidity/alkalinity), nitrogen, potassium, and phosphorus are particularly important in the prediction of yield levels. Soil type is another parameter that is often determined by a site visit.

Remote sensing is becoming increasingly important to precision agriculture. Early data that came from random satellite observations had low resolution and limited value. Now specially equipped satellites and aircraft may be hired to collect specific crop or soil information. Crop growth or health may be deduced from these data. Certain wavelengths of the electromagnetic spectrum are particularly helpful. The visible light frequencies provide some information. Unhealthy crops tend to reflect more yellow and red light. Various frequencies in the infrared range also have been correlated with plant health and soil moisture conditions. Multispectral systems provide data on the visible spectrum (often three primary colors) and a limited range of the infrared. More sophisticated equipment, called hyper-spectral, can provide data from a much broader range of the spectrum and from narrower sample bands. This type of data offers greater opportunity to correlate specific crop or soil conditions to measured spectral data.

Other types of remote sensing are becoming available. Light detection and ranging (LIDAR), e.g., is a laser

ranging technique that may be used to measure topography and plant height simultaneously.^[19] By applying to the forest industry and relatively expensive, this method holds promise for rapid feedback of information on crop growth problems to the producer, perhaps allowing solution of the problem before yield is permanently affected. For example, nematodes in soybeans are a common cause of reduced vigor and yield if left untreated. Conventional crop scouting or remote sensing may not detect small areas of infestation or provide feedback in time to take corrective action. With regular LIDAR imaging, a producer could detect and treat such trouble spots in a timely and efficient manner.

GEOGRAPHIC INFORMATION SYSTEMS (GISs)

GIS techniques are an integral part of precision agriculture. Basically, GIS is a storage system for geographically referenced digital data. Many of the data types discussed above can be digitized (if not already in digital form) and referenced to specific locations in a field. Each parameter or variable then may be represented as a layer of information. Geographic position of the information matches the position on a map of the field. The value of a parameter may be represented on a map as a shade of gray or a color. So a GIS information layer representing soil type can be drawn in the physical shape of the field with patches of color—each color representing a different soil type. Many such layers may exist in a GIS data set for a particular field. Depending upon the need, these layers may be viewed as overlays—simultaneous presentation of several variables in one field. As many layers of information are added to the GIS system, it becomes apparent that human vision is inadequate to detect the important patterns. Computers, however, are infinitely more able to “see” data patterns with a potential to produce an economic advantage.

FUTURE

The future of precision agriculture depends on economic results. Can the cost of additional equipment and operations be more than offset by increased economic return and value of environmental protection? It seems possible that all agricultural operations could be monitored and recorded, linked by digital transmissions to databases containing weather, remote sensing, and historical data, and controlled through a general model of the crop’s predicted response to specific inputs. Such a system may not only control specific agricultural operations but also be involved in scheduling, ordering seed, fertilizer, and supplies, providing records to regulating agencies, and feeding valuable information back into the research system for further refinement of the control model. Already, manufacturers are producing prototype agricultural machines that perform without an operator. These machines are guided by GPS, are controlled by

computer, and have onboard sensors to detect obstructions or people in the way. The advancement of agriculture will come with technology—technology to feed the world.

Precision Agriculture: Fertilization

Silvia H. Haneklaus

Ewald Schnug

Institute for Crop and Soil Science, Julius Kuhn Institute (JKI), Braunschweig, Germany

Abstract

Soils are neither static nor homogenous in space and time, and this directly influences the concentration of plant-available nutrients and, consequently, the small-scale spatiotemporal variation of the fertilizer demand. Precision agriculture comprises the technology to determine the spatial variation of soil and plant features and to transfer this information into site-specific field operations. Variable rate fertilization within precision agriculture is applied to match spatially distributed nutrient pools and fluxes with fertilizer rates. In comparison, a uniform treatment of fields causes inevitably nutrient surpluses and undersupplies and thus is neither ecologically sound nor economically viable.

INTRODUCTION

The fertilizer rate is usually calculated from the balance between the natural supply by soil and environment, the nutrient demand of the crop, and the inevitable losses to the environment. The agricultural production system fulfills the criteria of sustainability if the losses in this balance can be minimized while maximizing crop productivity and economic profits. The major obstacles to achieving this ideal case of adjusting nutrient balances are, first, the accuracy of the methods employed to quantify the contribution from the soil, to determine the physiological requirement of the plant, and to calculate the losses to the environment; second, to address the spatial variability of soil fertility parameters and to match it with variable fertilizer rates; and, third, to warrant the profitability of implementing the technology.

GEOREFERENCED SOIL AND CROP INFORMATION

Access to validated georeferenced data is a major obstacle to the further development of precision agriculture. The applicability of different data sources mainly depends on the scale of farming. Big farms usually operate on a distinctly higher level of technology than small farms. Thus, big farms rely on access to digital data covering large areas. In comparison, on small farms, local knowledge is an important source of information, providing data in the form of amateurish maps, field files, and any other materialized form of store.^[1]

For variable rate fertilization, only maps with a scale of >1:5000, preferably in digital form, provide suitable information.^[2] Particularly in undulated areas, terrain

information is an important data source, and digital terrain models may be processed from elevation data or can be assessed directly on the farm.^[1] Experiences from grid soil sampling reveal that it is superior to random sampling because of the spatial correlation of values.^[3] Relevant in this context is that optimum sampling distances vary in different landscapes, depending on the scale of variation of field characteristics as a result of parent material and pedogenesis.^[4] The disadvantage of grid sampling is that it is time-consuming, labor-consuming, and costly. Strategies that reduce sampling efforts are, for instance, directed sampling and self-surveying.^[2]

In principle, remotely sensed data offer a fast and economic way to optimize soil and plant sampling strategies and to design variable field management. For variable rate fertilization, it is vital that the difference between nutrient demand and actual nutrient supply be determined in time, which is a major handicap because of the problem of cloud coverage at phenological relevant growth stages, the restricted revisit time of satellites, and the physical availability of airplanes. This would require the real-time surveillance of crops. Low-Altitude Stationary Surveillance Instrumental Equipment is an innovative concept for the continuous recording of real-time images of crop and soil surfaces, which are automatically rectified and georeferenced in a geographic information system.^[5]

On-the-go sensors for assessing the spatial variation of soil water, nitrate, organic matter, pH, electrical conductivity, and soil texture exist.^[6] One of the most promising developments in generating data for variable rate fertilization is the yield sensor because nutrient removal from a field is an important information for making decisions for variable rate fertilization. Another major field of application is the evaluation of the plant nitrogen status; here,

fundamental objections exist because of principal incorrect assumptions.^[1]

DECISION-MAKING STRATEGIES

Recommendation Schemes

Common rules for fertilizer application have been proposed for decision making and were directly transferred into fertilizer rates. However, there are two major criticisms of such approach. First, the basic fertilizer response curves were mainly established in the 1940s–1960s, and databases need to be updated and validated.^[7] Second, established critical thresholds refer to small homogenous plots and are counterproductive with view to the target, which is to identify variability, to match it with a variable input, and to improve recommendations.^[7] Additionally, soils and plants were sampled in the past without reference to spatial autocorrelation, so that the whole system of interpretation used for recommendation is based on averages, too.^[8]

On-Site Experimentation

Using precision agriculture technologies for positioning, variable rate application, and on-line yield measurements, it is possible to investigate multivariate experimental designs on each farm including the whole bandwidth of ecological variability.

One of the first and most crucial steps in decision making is the ranking of the nutritional minimum factors of a site. A suitable approach to identify yield-limiting factors in the mineral nutrition of a particular site is the directed sampling in high-yielding and low-yielding areas.

Ideally, fertilizer rates are calculated on the basis of response curves. The boundary line development system is a suitable tool to establish site-specific response curves from georeferenced yield and soil/plant data.^[1]

ACCURACY OF TECHNICAL EQUIPMENT AND DATA

In general, the risk that a mismatch of information and field operations causes adverse effects increases the smaller in the distance between two significantly different spatial events. A great problem to define quality criteria for variable rate fertilization is variability, which is searched for, so that erroneous variability can easily be hidden.

Data summarized in [Table 1](#) reveal that the accuracy of georeferenced information should no longer be a problem. The guaranteed quality standards for purchasable information are also satisfactory. The greatest source for errors will still be failures by the operator. Satellite-aided navigation of fertilizer spreaders meets the same accuracy than positioning (see [Table 1](#)).

Table 1 Positional accuracy of different data sources and technical equipment for variable rate fertilization.

Source	Positional accuracy (m)
Satellite positioning	
Standard	2–3
Differential	<1
With S/A	25
Ordnance survey maps	
Maps (scale 1:5000)	3
Digital elevation data	0.5
Soil survey	
Digitizing of map features (sampling points)	3
Boundaries of choropleth maps	15–20
Remote sensing images	10–20
Yield maps	10–15

Source: From Capelle.^[2]

The precise match of position and variable rate with the data of the fertilizer map is more problematic. The error during variable rate application of fertilizers has several main components such as the error of the navigation system, the hysteretic effect between the time where the system is advised to apply a certain amount of fertilizer,^[9] unevenness in the lateral distribution pattern,^[10] and inhomogeneities in the fertilizer material itself.^[11] Depending on the fertilizer used and the application system employed, more or fewer errors can occur. In general, the relative size of this error increases in the following order: liquids < solids; manufactured fertilizers < farm sources; slurries < manures; pneumatic spreaders < spin disk spreaders; and irrigation < spreading.^[10,11] The great number of error sources and non-spatial variability supports the hypothesis that successful variable rate fertilization requires the development and implementation of quality standards and control measures to enabling the secure implementation of the concept for farmers.

Saved fertilizer inputs or prevented environmental costs will not pay for the implementation of precision agriculture technologies.^[1] On average, fertilizer savings ranged from 10% to 20%, but yield increases varied only between 3% and 5%.^[1] The intrinsic hypothesis for the environmental friendliness of variable rate fertilization is evident because less fertilizer is applied to areas with increased vulnerability to nutrient losses. Only a few experimental proofs with direct measurements are available. Whitley et al.,^[12] for instance, found that the variable rate nitrogen fertilization of potato increased nitrate fluxes in the surface soil by 33%, whereas those in the subsurface soil were not affected. At the same time, the nitrate content in the soil was lower when rates were applied variably, resulting in an increased nitrogen utilization efficiency of the crop.

CONCLUSION

Agriculture was associated positively with food production and food security less than a century ago. It is commonly linked to problems such as the eutrophication of water bodies and enrichment of pesticides in soils and plants. Precision agriculture technologies could be an important step to regain the confidence of consumers by limiting the input of fertilizers and agrochemicals to the minimum requirements. This minimum equals fertilizer rates that are sufficient to maintain the site-specific crop productivity, whereas nutrient losses come close to those in low-input systems such as organic farming. Last, but not least variable, rate fertilization needs to be profitable, but reduced fertilizer expenditures and yield increases will not justify the costs for implementing the technology. Therefore, other profitable applications such as weed control measures and improved logistics and traffic on the field must pay for the change in the production system.^[1]

Precision Agriculture: Nutrient Cycling

Robert J. Lascano

*U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS),
Lubbock, Texas, U.S.A.*

Abstract

Precision farming, also known as site-specific management, refers to the practice of applying agronomic inputs, mainly fertilizers and other chemicals, across a farm at variable rates based on soil nutrients or chemical tests, soil textural changes, weed pressures, and yield maps for each field in the farm. The technology for crop yield mapping is more advanced than methodologies for determining and understanding causes of yield variability. As the cost of agronomic inputs increase, producers will likely adopt variable rate strategies and manage their crops to increase crop yield and to maximize profitability.

INTRODUCTION

“Precision farming,” also known as site-specific management, refers to the practice of applying agronomic inputs, mainly fertilizers and other chemicals, across a farm at variable rates based on soil nutrients or chemical tests, soil textural changes, weed pressures, and/or yield maps for each field in the farm. In most large fields (e.g., >40 ha), crop yield is notoriously variable. The sources of this variation are related to the physical and chemical properties of the soil, pests, microclimate, genetic and phenological responses of the crop, and their interactions. The technology for crop yield mapping is more advanced than methodologies for determining and understanding causes of yield variability. Prevailing and traditional management practices treat fields uniformly as one unit. However, reports^[1–3] show that to understand underlying soil processes that explain crop yield variability, research must be done at the landscape level and using appropriate statistical tools for large-scale studies.^[1,3,4]

BACKGROUND

There is a linear relation between crop yield and water use when the only limiting factor is water;^[5] however, root uptake of water is synergistically related to nutrient uptake and the two processes cannot be separated. Precision farming has the potential to improve water and nutrient use efficiency on large fields provided that there is a quantitative understanding of what factors affect crop water and nutrient use and where in the field. It is known that crop water and nutrient use are a function of many biotic and abiotic variables—including managed inputs—and

that harvestable yield is a manifestation of how these variables and inputs interact and are integrated during the growing season. However, it is difficult to determine a hierarchy of the contribution of each input and variable to the measured yield using classical statistics.^[2,3] Often, variables that affect water and nutrient supply to the plant contribute to yield at a high level assuming an adequate plant stand and weed control. The cause and effect relation between a single state variable and crop yield is site specific and is difficult to establish without considerable sampling of the soil and/or crop. The establishment of response functions, i.e., crop water and nutrient use as a function of variable x_i , only gives a partial answer to explain crop water and nutrient use and yield based on inputs. The general idea of precision farming is to optimize input application to the measured crop yield at each sampling location. This is a simple premise; however, the decisions for variable rate application of any agronomic input must consider temporal and spatial variability of the soil's properties affecting crop growth, water and nutrient use, and yield. Soil factors that affect stored water, such as depth to root restricting layer and soil textural differences, must be considered in any precision farming operation that attempts to improve crop water use and yield related to agronomic inputs. Similarly, to improve the use of any soil macro- and micronutrient by the crop, the overall cycle of the nutrient must be considered, including its availability in the soil and demand by the crop.

Precision farming must incorporate the inherent spatial and temporal variability of soil physical, chemical, and biological factors within a field for input management. Accurate representation of spatial and temporal variability in a field requires taking and analyzing many samples. Sampling is normally done on a grid with a scale that can vary from one to several hundred meters.^[6] Once properties

are measured, geostatistical tools (e.g., semivariogram, kriging, and cokriging) and other spatial statistical tools (e.g., autocorrelation, crosscorrelation, and state-space analysis) can be used to establish statistical relations in space and to minimize the number of soil samples to characterize and map fields.^[2,3,7] The number of samples required *a priori* to determine spatial and temporal variability is perhaps the single largest deterrent in the application of precision farming practices to manage and improve crop water and nutrient use.

There is very little information published on crop water and nutrient use across large fields at the landscape level and in the context of precision farming.^[1,8,9] An exception is a study,^[1] where cotton water and total nitrogen use were measured along a 700 m transect with the objective to: 1) illustrate the landscape pattern of cotton water and total nitrogen use and 2) determine the underlying soil processes governing cotton lint yield variability. In this study, state-space analysis^[1,3] is used to formulate management decisions that may improve crop water and nitrogen use and, thus, the yield, using precision farming practices.

LANDSCAPE CROP WATER AND NITROGEN USE

The concept of crop water and nitrogen use in a large field is illustrated by the study of Li, Lascano, et al.^[1] In 1999, a field experiment was conducted near Lamesa, Texas, on a research farm of Texas A&M University on the southern edge of the High Plains of Texas. The soil was classified as an Amarillo sandy loam. The field was 60 ha with slopes ranging between 0.3% and 6.3%.^[1] To assess the effect of soil water, nitrate-nitrogen ($\text{NO}_3\text{-N}$), and topography on cotton lint yield across the landscape, two irrigation levels were used. The irrigation treatments consisted of water applications at the 50% and 75% potential evapotranspiration (ET) with a center pivot low energy precision application (LEPA) irrigation system.^[10] At each irrigation level, one transect was established following the circular pattern of the center pivot. The two transects were instrumented with 50 neutron access tubes that were 15 m apart from each other, and volumetric water content (θ_v) was measured periodically throughout the growing season. At each point θ_v was measured in 0.3 m depth increments to a depth of 2.0 m using a neutron probe calibrated for this soil. In addition, at each transect point soil texture, soil and plant $\text{NO}_3\text{-N}$, leaf area index, lint yield, slope, plant density, and other parameters were measured.^[1]

It has been shown that the use of classical statistics, such as regression analysis and analysis of variance, fails to completely explain the cause and effect between, e.g., crop yield and measured soil variables in precision farming experiments.^[1-4,11] Instead, there are other more appropriate statistical tools for relating the variability of

soil and plant parameters measured in space and time. For example, the structure of the spatial variance between measurements may be derived from the sample “semivariogram,” which is the average variance between neighboring measurements spatially separated by the same distance. Spatial structure between variables is often determined using “autocorrelation” and “crosscorrelation” functions. Autocorrelation measures the linear correlation of a variable in space along a transect. Crosscorrelation is the comparison of two variables measured along a transect and is used to describe the spatial correlation between two landscape variables, i.e., where one variable, the tail variable, lags behind the head variable by some distance. The spatial association between several variables can be described using “state-space analysis,” which is a multivariate autoregressive technique.^[1-4,7,11]

To illustrate the variability of crop water use or ET, values measured along the 50% irrigation transect were selected.^[1] In Fig. 1, the relation between the scaled ET and elevation, where both are given as a function of distance along the transect, is shown. The ET data are scaled to the maximum of 426 mm of water measured 210 m from the south end of the transect. These results show that higher ET was measured at lower elevations and that ET decreased at higher elevations. Spatial crosscorrelation between lint yield and soil water, lint yield and site elevation, and soil water and site elevation is shown in Fig. 2. For a 95% confidence interval, the cotton lint yield was positively crosscorrelated with soil

Fig. 1 Scaled evapotranspiration and elevation as a function of distance along a 700 m transect.

Fig. 2 Crosscorrelation as a function of lag distance: (A) Lint yield and soil water; (B) lint yield and elevation; and (C) soil water and elevation. Shown is the 95% confidence for the cross-correlation distance.

Source: From Li, Lascano, et al.^[1]

θ_v across a lag distance of ± 30 m. Lint yield and θ_v were negatively crosscorrelated with elevation at a lag distance of ± 30 m. These results show the effect of topography on the θ_v and crop water use measured along the transect. Similar results are given in other reports.^[1,8,9,11] In this example the crosscorrelation between θ_v and elevation shows the spatial structure of measured variables and further that more water was stored in lower elevations resulting in higher ET.

Linear regression analysis between θ_v and lint yield and relative site elevation is shown in Fig. 3, and the state-space analysis for the relation between lint yield and three measured parameters is shown in Fig. 4. Results in Fig. 3 show the shortcomings of using an inappropriate statistical tool to understand underlying processes explained with the state-space analysis. This analysis (Fig. 4) quantified how cotton lint yields varied as a function of distance and showed that by using θ_v , soil $\text{NO}_3\text{-N}$, and elevation the variation in lint yield can be explained with a high level of confidence.

Benefits of precision farming to improve crop water and nutrient use may be obtained by an economic analysis of

Fig. 3 Soil water content (θ_v) and cotton lint yield as a function of site relative elevation.

maximizing crop yield as a function of application of N fertilizer and irrigation water as given by the state-space equation. In the example given, the decision can be made to apply more N fertilizer to the lower areas of the field that also hold more water and increase crop water use and yield. With the introduction of variable rate planters, it will be possible in the near future to discriminate site locations and plant more “drought” tolerant varieties or change the seeding rate in areas that are prone to have less soil water. This implies the delineation of management zones within a field that are defined based on potential crop water and nutrient use and their interaction with other input variables to maximize economic yield across the field. This type of precision farming is not practiced but remains within the realm of possibilities that this type of farming has to offer.

Fig. 4 State-space equation relating cotton lint yield (Y) to water content (W), nitrogen (N), and elevation (E) as a function of distance and location (i) along a 700 m transect.

Source: From Li, Lascano, et al.^[1]

A final consideration is the cost/benefit of precision agriculture practices and its impact on agriculture. Hardware for variable rate application of agronomic inputs is relatively expensive and in many cases unavailable; however, with increased adaptation and use of these practices the cost will be reduced. Further, environmental concerns for a given area will probably place limits on the amount of certain nutrients, e.g., N fertilizer, used for crop production. This will force producers to apply N and other nutrients across the field according to crop needs and position along the landscape. These practices will be beneficial from both an environmental and an economical point of view.

CONCLUSION

As the cost of agronomic inputs increase, producer's will likely adopt variable rate strategies and manage their crops to increase crop yield and to maximize profitability.

Abstract

Remote sensing has been used in various investigations to determine the variability of soil parameters. Soil reflectance in the field is affected adversely by factors such as soil water dynamics, soil roughness, and surface effects because of cultivation practices. The interaction between all these factors reveals that ground truth campaigns are a prerequisite for calibrating reflectance data. Furthermore, complex algorithms need to be elaborated to correct interfering factors. Only then can reliable recommendations for farm management decisions be expected. Noteworthy is that with the exception of the radar technology, the penetration depth of the recorded reflectance is extremely small. Usually agricultural investigations comprise the whole top soil layer. Other problems such as the availability of sensor and platform, weather conditions, spatial, spectral and temporal resolution of data, trained operators, and, last but not least, cost-effective provision of data sets have to be overcome before remote sensing can be used extensively for data acquisition. Despite these basic restrictions, remote sensing has a high potential to identify in-field variation of soil features as large areas can be surveyed, which is not feasible by any other technique.

INTRODUCTION

Fertile soils are one of the most important resources on earth. Plant production practices such as fertilization, ploughing, and sowing are often applied in rates following certain soil parameters. Soils are heterogeneous in space and time so that the common way of uniform fertilizer application rates results in, side by side, oversupply and undersupply. Precision agriculture is an innovative farm concept, which uses modern techniques of geostatistic, geographic information systems, and global positioning systems for an ecologically and economically optimized use of agricultural inputs. Adoption of precision agriculture is unlikely to be uniform across farm types and sizes. Numerous factors such as soil variability, field sizes, and economical and technological possibilities influence the decision for or against precision agriculture.^[1] Mainly big farms with large fields and certain soil variability are interested or have already installed precision agriculture management systems. The efficient

acquisition of geocoded soil information is a major obstacle to the implementation of precision agriculture technologies. Soil information data sampled at densities that reflect the scale of spatial variability are required for the development of soil maps and decision support strategies to develop variable rate algorithms (e.g., for fertilizer applications).

Remote sensing is an efficient tool for retrieving information on large regions including data on spatial soil variability. Most agricultural fields have periods without vegetation so that the bare soil is visible, but the date depends on crop species and crop rotation. Bare soils can be found usually in the late autumn and early spring in Central Europe. However, with regard to remote sensing, these periods are unfavorable because of low sun elevation, which causes additional illumination and shading effects in the imagery.

In laboratory studies under standardized conditions, relationships were found between reflectance data and soil parameters such as soil organic matter, soil moisture,

particle size, mineral composition, iron oxides, soluble salts, and parent material. The three major factors causing soil heterogeneity on agricultural fields are soil organic matter, soil texture, and soil water regime. Therefore, this entry focuses on these parameters.

DATA SOURCES

The availability of a multitude of sensors and platforms results in a wide variety of remote sensing systems for data acquisition (Fig. 1). Not all sensor–platform combinations are operational, but theoretically, each sensor could be installed on each platform.

Sensors usually operate with wavelengths between 0.3 μm and 1 m. In general, four wavelength sections can be distinguished, namely: visible (0.4–0.7 μm), reflective infrared (0.7–3 μm), thermal infrared (8–14 μm), and microwave (1 mm–1 m). The geometrical resolution and distortion depend on the sensor system. Analog imagery can be transformed into digital data using scanning systems. The available remote sensing techniques are described in more detail by Richards and Jia^[2] and Lillesand and Kiefer.^[3] Soil reflectance measurements in the field are burdened by problems such as variations in illumination, viewing angle, and soil roughness. In particular, in two narrow ranges at about 1.4–1.9 μm , atmospheric water effects are problematic, besides the superimposing absorption features of gases.^[4]

SOIL ORGANIC MATTER

Soil organic matter is one of the most important soil fertility parameters of agricultural soils. In-field

variability of soil organic matter causes heterogeneous soil productivity. Coefficients of variation of 25–30% were determined.^[6] Thus, the determination of the variability of soil organic matter is essential for developing variable rate strategies, for instance, for fertilization and pesticide input.

The strong influence of soil organic matter on soil reflectance is described by Baumgardner et al.^[7] and Irons, Weismiller, and Petersen.^[8] If the soil organic matter content is higher than 2%, wavelengths of 0.4–2.5 μm proved to be suitable to establish quantitative relationships under laboratory conditions.^[7] Remotely sensed images are not used to map the variability of soil organic matter for precision agriculture^[9] because other factors such as soil moisture and surface roughness strongly influence the spectral reflectance and its suitability under practical conditions (Fig. 2). However, the variation of reflectance within fields can be used for directed sampling campaigns followed by laboratory analysis, resulting in information on spatial variation of soil parameters such as soil organic matter.^[10] A case study of McCann et al.^[11] described the use of reflectance characteristics of bare soil images to define management zones that need to be verified by ground truth campaigns.

SOIL TEXTURE

In rainfed agriculture, soil texture is the major factor influencing the effective field capacity. Particle size distribution, soil structure, and surface roughness affect the spectral reflectance. In single-factorial experiments, a decreasing particle size resulted in an increase of reflectivity.^[8] However, under field conditions, clayey soils often appear darker than sandy soils although the particle

Fig. 3 Influence of major soil fertility factors on the reflectance of remotely sensed images.

size of clay is $<0.2\text{--}2\text{ }\mu\text{m}$, distinctly smaller than that of sand ($63\text{--}2000\text{ }\mu\text{m}$).^[12] The reasons are differences in mineralogy, the fact that clay forms agglomerates that are larger than sand grains, and the superimposition of soil moisture and soil organic matter.^[8] Fig. 3 illustrates the problem of superimposition of the major soil fertility parameters on the reflectance in a simplified scheme.

Extensive ground truthing is required to verify reflectance data. As soil texture is a constant soil parameter, ground data acquisition is required only once so that remote sensing could be an efficient tool for precision agriculture. However, at the moment, remotely sensed images are not used to map soil variability on an operational basis.^[9]

SOIL MOISTURE

As mentioned before, soil water regime is an important characteristic for the assessment of variability of soil fertility. Major problems in recording soil moisture are its dynamics and, again, the superimposition of the reflectance characteristics by other soil features (Figs. 2 and 3). Active radar sensing and passive radar sensing were used successfully to measure differences in soil moisture.^[13] (See also the entry *Water Content: Passive and Active Microwave Remote Sensing*, p. 2480.) Remote sensing in the microwave sector has substantial advantages compared with optical remote sensing techniques. The wavelengths penetrate clouds, haze, and light rain so that image acquisition is more or less independent of weather conditions. The microwave signal is not affected by solar illumination angles, resulting in bidirectional reflection effects. However, other problems such as geometrical distortion (e.g., layover and foreshortening) have to be considered. With respect to its use in precision agriculture, passive radar data are not available at an adequate spatial resolution. In comparison, it is possible to record the in-field variability of soil moisture by active radar.^[14] Here, the sensitivity to superimposition effects by soil roughness and vegetation

density limits the practical application for precision agriculture.

CONCLUSION

Remote sensing was used in various investigations to determine the variability of soil parameters.^[9] In laboratory studies, unifactorial experiments provided usually good results, whereas measurements under field conditions revealed clearly problems because of the superimposition of soil parameters. Soil reflectance in the field is affected adversely by factors such as soil water dynamics, soil roughness, and surface effects because of cultivation practices. The interaction between all factors reveals that ground truth campaigns are a prerequisite for calibrating reflectance data. Furthermore, complex algorithms need to be elaborated to correct interfering factors. Only then can reliable recommendations for farm management decisions be expected. Noteworthy is that with the exception of the radar technology, the penetration depth of the recorded reflectance is extremely small. Usually, agricultural investigations comprise the whole top soil layer. Other problems such as the availability of sensor and platform, weather conditions, spatial, spectral and temporal resolution of data, trained operators, and, last but not least, cost-effective provision of data sets have to be overcome before remote sensing can be used extensively for data acquisition. Despite these basic restrictions, remote sensing has a high potential to identify in-field variation of soil features as large areas can be surveyed, which is not feasible by any other technique.

Abstract

Forest ecosystems are dynamic systems that are continually undergoing changes and disturbances, whether they are natural or anthropogenic in origin. These disturbances influence soil pedogenesis and therefore soil productivity. Soil productivity is the capacity of a soil to support plant growth. The degree, type, and frequency of disturbance will variously affect plant growth through the changes they cause to the soil. A thorough knowledge of soil processes is therefore required to understand the potential effects of disturbances on productivity but with the understanding that short-term results may be different to long-term results in forest ecosystems.

INTRODUCTION

Disturbances are relatively discrete events, either natural or anthropogenic (i.e., human induced), that change the existing condition of an ecological system. Soil productivity refers to the capacity of a soil to support plant growth. Disturbances are an important process of virtually all forest ecosystems. It is not if a disturbance will happen but when, where, and how. Natural disturbances, such as fire, windthrow, insect and disease outbreaks, mass wasting (e.g., landslides), surface erosion, and catastrophic events (e.g., hurricanes, earthquakes, and floods), control forest succession and affect soil productivity. The influence of human activity has increased anthropogenic disturbances such as harvesting, mining, human-caused fires, air pollution (e.g., acid deposition), and climate change, which may affect forest succession and soil productivity. Human intervention (e.g., fire suppression) subsequently also has altered the frequency and degree of natural disturbances affecting soil productivity. How these disturbances alter soil processes and ultimately affect soil productivity depends on numerous factors, including the frequency, type, degree of disturbances, soil properties, and forest ecosystem.

The most obvious effect associated with disturbance natural or anthropogenic is the removal or destruction of aboveground biomass. However, changes as a result of disturbance may affect soil processes that result in either positive or negative changes to soil productivity. The changes in soil productivity from disturbance may be direct or indirect. They include changes to the chemical, physical,

and biological properties of the soil, such as loss of organic matter, soil compaction, soil displacement or mixing, exposure of subsurface material and bedrock, changes in nutrient supply, and soil organisms.

NATURAL DISTURBANCES

Fire

The most widely occurring and extensively studied natural disturbance is fire. Forest fires are a major large-scale disturbance in most forests of the world. These include temperate and boreal forests, most Australian ecosystems, Mediterranean-type ecosystems, and all but the wettest of tropical rainforests,^[1] including lowland rain forests of northwestern Amazonia.^[2] The intensity, type, and frequency of fire are important factors that affect soil productivity. High-intensity burns with high temperatures will result in volatilization of various nutrients. Carbon (C), nitrogen (N), and sulfur (S) will volatilize at relatively low temperatures (as low as 302°F to <932°F). Phosphorus (P) and potassium (K) are less volatile but will volatilize at temperatures of more than 1112°F. Losses of other non-volatile nutrients (>1832°F) such as calcium (Ca), magnesium (Mg), and manganese (Mn) may occur through blowing of fine ash. Similarly, in low-temperature burns, P also can be lost through the removal of fine ash. The accumulation of cations (e.g., Ca and Mg) has been observed in surface soils following high-intensity fires and results in increased soil pH.

Soil biological processes also may be influenced by fire, either directly by affecting soil organisms or indirectly as a result of chemical changes. It is difficult, however, to assess the relative influence of fire on soil biological processes. Some soil organisms are killed in ground fires, thus the species composition of the soil fauna and microbial population may change. This could indirectly influence soil productivity by affecting the microbial population of the soil (i.e., mycorrhizal fungi), thus altering the rate of nutrient release from the soil.

In the short term, fires can increase nutrient availability by releasing those tied up in soil organic matter (humus). This is probably beneficial; however, under certain conditions (e.g., relatively infertile soils), organic matter and nutrients may be lost that could decrease the long-term productivity of the soil.^[3] Fire is rarely a uniform event, and, generally, large burns have a variety of intensities across the landscape. Thus, generalizations are not entirely appropriate, although fire disturbance is considered essential to the rejuvenation of most forest ecosystems through the release of nutrients found in humus and renewal of forest stands.

Erosion

Surface erosion would be expected to be low in natural forests. Significant surface erosion may result from natural disturbances such as landslides, intense fires, and anthropogenic disturbances, which remove vegetative cover and expose mineral soil. Mass wasting (e.g., landslides and snow avalanches) is a natural process in mountainous areas and steep terrain. Generally, mass-wasting events tend to have longer lasting effects on soil productivity, because surface soil is often removed or severely disturbed. The soils on upper portions of slides generally are shallower and coarser with more bedrock exposure than the original soils. The lower portion of slides consists mainly of materials deposited or mixed with original soil. Additionally, for several years after failure, slides are susceptible to surface erosion. Revegetation of slide areas generally occurs on modified rather than primary soil materials. Productivity of these areas is reduced, although in many cases colonizing plant species are similar to adjacent areas.

Windthrow

Gaps are the most obvious result of windthrow, but soils can also be affected^[4] by altering structure and mixing subsurface soil with surface material. In some forests, small-scale gaps are the dominant canopy disturbances between large-scale events such as fire.

Mixing of soil may affect nutrient availability and soil-forming processes and expose a variety of substrates that may negatively affect surface soil chemical and physical properties. In boreal forests, long-term effects of windthrow may persist for 100–200 years.

Insects and Disease

Insects and disease indirectly accelerate or change soil nutrient dynamics. These processes include 1) altering the rate and amount of nutrients leached or deposited as litter; 2) changing light intensities; 3) reducing competition among plants; 4) altering plant species composition; and 5) stimulating translocation of nutrients from boles and branches to high turnover components such as leaves, buds, and flowers.^[5] Insect grazing occurs more slowly than obvious disturbances such as fire or forest harvesting. Similarly, pathogens (i.e., disease organisms) also differ from large-scale disturbances by selectively eliminating less vigorous individuals.^[6] The influence of insects and diseases, however, is similar to large-scale disturbances in that they recycle nutrients and renew forest stands within the landscape. Pathogens and, to some extent, insects can also increase tree susceptibility to windthrow and fire, which will affect soil productivity as outlined previously.

ANTHROPOGENIC (HUMAN-INDUCED) DISTURBANCES

Harvesting

The most common human-related activity is harvesting and its associated practices. The influence on soil productivity will vary greatly among species (forest type), time of harvest, and inherent soil properties.

Biomass removal is the main pathway for nutrient loss from harvesting. Losses will depend on the type of harvest (e.g., whole tree vs. boles only), harvest system used (e.g., clear cut vs. selective logging), forest type, and time of year. Generally, the influence of forestry practices on nutrient loss is long term, and harvesting rotation times that are less than the time needed to replace lost nutrients will eventually reduce soil productivity. The primary N sources in forest soils are biological fixation or deposition from the atmosphere. In most temperate and boreal forests, loss of N and soil processes related to N availability is the most critical. Availability of most other nutrients other, however, is largely dependent on weathering of parent material. In some temperate and boreal forests, particularly those affected by acid deposition, the loss of cations, particularly calcium (Ca), also may reduce soil productivity.^[7]

Some tropical forests, such as tropical montane forests, appear to function similar to temperate and boreal forests with respect to N.^[8] However, in highly weathered clay soils of the tropics (e.g., Oxisols and Ultisols), there is little replacement of nutrients lost.^[9] In these forests (i.e., lowland rain forests), changes in the phosphorus P cycle (and possibly Ca) following harvesting may be the most critical process affecting soil productivity.

Increased leaching (less nutrient uptake and lower evapotranspiration) is another pathway for nutrient loss following harvest. In most studies of temperate and boreal forests, nutrient loss from increased leaching in harvesting does not appear to have a major influence on soil productivity in the short term.^[10]

Deforestation through anthropogenic fire (i.e., slash-and-burn agriculture) and land clearing is a special type of harvesting disturbance of particular concern in tropical forests. This phenomenon has contributed to reduced productivity across a number of tropical soil types and forest ecosystems including the Amazon.^[11] Following land clearing involving fire, loss of organic matter and nutrients is generally more rapid and complete in tropical forests than in temperate or boreal forests.^[12] This is believed to be caused by a combination of the climate, easily decomposable organic matter, and reduced organic inputs. In nutrient-poor ecosystems, disruption of the nutrient conservation processes will quickly result in reduced productivity following land clearing. Nutrient-rich sites do not lose their potential productivity in the short term, but the long-term implications are still a concern.^[13]

Other important factors affecting soil productivity in harvesting are soil compaction, displacement, and organic matter loss. Altered soil physical properties from forestry practices represent deviations from the natural range of soil conditions, usually with negative effects on soil productivity.^[14] Physical disturbances associated with harvesting, including roads, skid trails, and landings, may result in soil compaction, soil displacement and mixing, exposure of unfavorable subsurface material, and organic matter removal.

Soil compaction is a concern in virtually all forest ecosystems.^[15] Tracked areas generally have lower soil productivity because of soil compaction and possibly soil displacement (including removal of organic matter). Generally, the loss of productivity is related to the amount of compaction. Compaction affects soil structure, aeration, water infiltration, runoff, and surface erosion that will reduce soil productivity. Recovery of compacted soils is dependent on several factors and has been found to vary from several years to several decades in boreal, temperate, and tropical forests.^[15] In contrast, tree growth has been found to be higher on displaced material such as berms and sidecasts compared with the harvested undisturbed soils. This has been related to improved edaphic conditions (e.g., aeration and porosity), increased soil organic matter, and lack of vegetative competition.

Site Preparation

Site preparation is used to produce more appropriate seedbeds for seedlings. In the short term, soil productivity may be improved. However, potential detrimental factors as a result of organic matter and nutrient loss could have long-term effects. The severity of disturbance is related to the

degree of organic matter and nutrient losses as a result of mechanical site preparation.^[3]

Mining

Mining produces large amounts of waste material and disrupts the biogeochemical cycles (e.g., water, carbon, and nutrient cycles) within the local landscape and therefore causes losses in soil productivity. Reclamation practices are determined by a thorough knowledge of forest conditions predisturbance and an understanding of how to reintegrate the disturbed area into the surrounding landscape. Fundamental to reclamation is the type of soil used and the soil's physical, chemical, and biological properties.^[16] Establishment of soil productivity and a natural climax of forest succession following land reclamation is unique to each site where (as noted in Harvesting above) tropical, temperate, and boreal soils have undergone different soil-forming processes and each area therefore requires different considerations. For example, coarse-textured acidic soils were best for subsequent tree growth in the temperate Appalachian Mountains.^[17] While in the western boreal forest, landscape level variability was shown to be an important consideration in reclamation.^[18] Restoring soil productivity with resilience and landscape integrity are the objectives of ecosystem reclamation; however, there is a growing understanding that novel and not natural ecosystems may develop.^[19]

Acid Deposition

Acid deposition is a large-scale (i.e., regional or greater) disturbance that may influence soil productivity. Acid deposition is decreasing in many parts of the world; however, it remains a concern in most of Europe and eastern North America and is of increasing concern in many countries such as China. In high-deposition areas, soil acidification, reduced base cations in surface soils, increased aluminum, and nutrient imbalances (particularly N saturation) have been observed. The loss in soil productivity will depend on the amount of soil acidification and the inherent physical and chemical properties. For example, the influence of acid deposition on the soil productivity of a sandy soil with low-cation exchange capacity will probably be greater than on a fine-textured soil with high-cation exchange capacity.

Climate Change

The spatial scale of climate change is similar to acid deposition; however, the potential influence of climate change on soil productivity is largely unknown. Changing climatic conditions may directly influence biological and chemical processes and thus influence soil productivity. Indirect effects include changing the frequency and degree of natural disturbances.

CONCLUSION

Disturbances are important processes that affect forest ecosystems. Increasingly, human activities have resulted in changes to the frequency, type, and degree of disturbance on forest ecosystems. Disturbances influence the physical, chemical, and biological properties of soil, and changes to these properties subsequently affect soil productivity. The difficulties in assessing changes associated with disturbances are that forest ecosystems are evolving and not static, and available information is usually based on short-term results that may not be indicative of long-term effects. Thus, a fundamental understanding of the soil physical, chemical, and biological processes is needed to assess the consequences of natural or anthropogenic disturbances on soil productivity.

Protection: Policy of the European Union

Irene L. Heuser

Department of International Affairs, State Chancellery of the State of Brandenburg, Berlin, Germany

Luca Montanarella

European Commission, Joint Research Centre, Institute for Environment and Sustainability, Ispra, Italy

Abstract

Although different European Union (EU) policies (for instance, on water, waste, chemicals, industrial pollution prevention, nature protection, and pesticides) are already contributing to soil protection, they are not sufficient to ensure an adequate level of protection for all soils in Europe. This is due to the fact that legislation has not been orientated toward the different soil endangerment paths and the protection of the various soil functions. Therefore, the European Commission has developed a soil protection strategy in order to find answers to the most urgent soil threats, i.e., the priority threats of organic matter decline, soil erosion, and soil contamination as well as the additional aspects of sealing, compaction, decrease of biodiversity, salinization, and floods and landslides. The proposal for a Soil Protection Framework Directive sets out common principles for protecting soils across the EU and will help the EU Member States to better protect the soil on their territory and to use it in a sustainable way.

INTRODUCTION

The environment was a latecomer to the policy agenda of European integration. When the European (Economic) Community was founded in 1957, it concentrated on the quantitative dimensions of building the common market, with relatively little attention paid to its qualitative aspects. Meanwhile, air and water resources are protected by European Union (EU) law, whereas soil degradation is a serious problem in Europe. Soil performs a variety of crucially important functions for human life: 1) storage and buffering of pollutants and chemical compounds; 2) basis for food and fiber production; 3) storage of cultural heritage; and 4) source of raw materials. Soil degradation and its consequences are perceived only with considerable temporal delay because of the large resilience of soil systems to changes. Building up fully functioning soil layers of 30 cm requires a period of 1000–10,000 years.^[1] Therefore, soil is considered mainly as a non-renewable resource.^[2] In the EU, more than 150 million hectares of soil are affected by erosion, in the most extreme cases leading to desertification. Western Europe is highly urbanized and competition for the land available results in soil sealing. Moreover, soil contamination is a problem and 45% of the European soils have a low content of organic matter.^[3] Europe is characterized by great differences with respect to the soils' physical, chemical, and biological properties and more than 320 major soil types are reported on the soil map of Europe (Fig. 1). The common soil map^[4]

has helped to describe the high spatial variability. Furthermore, the majority of our soils are subject to private property rights. Owing to the threats to the soils of Europe, the European Commission has developed a soil protection strategy in order to find answers to these urgent questions. The following section investigates to which extent soil protection meanwhile is realized in the EU.

FEATURES OF EU SOIL PROTECTION POLICY

EU environmental policy and law have a huge impact on each Member State, with approximately 85% of national environmental legislation being derived from the Community. Although the Single European Act of 1987 established the possibility of enacting regulations about soil protection, this field has remained almost neglected. There is no comprehensive legal instrument dealing with soil protection. Theoretically, chemical, biological, and physical threats of the soils could be tackled by the objectives of Articles 174 ff. EC. [The extent and description of these environmental competencies will be preserved with almost the same wording according to the new Articles 191 ff. of the Treaty on the Functioning of the European Union which entered into force (as a part of the Lisbon Treaty) on December 1, 2009.^[5]] Any proposed legislation also has to take into account the complexity of environmental situations (e.g., different soil types) in the various regions of the Community.

Fig. 1 The distribution of major soil groups in Europe according to the World Reference base.

Source: From European Soil Data Centre, European Commission, 2008.

Community legislation on environmental aspects directly or indirectly affects the soils. The introduction of the Sewage Sludge Directive^[6] of 1986 forms the first legal instrument partly contributing to the protection of soils by regulating the use of sewage sludge in agriculture in such a way that it takes the plants' nutrient requirements and the quality of the soil into account. The 1996 Directive on Integrated Pollution and Prevention Control^[7] contains transmedial requirements on the operation of certain industrial plants, in particular permission provisions for larger

industrial plants on the basis of the application of the best available technique. (In December 2007, the Commission proposed a new directive on industrial emissions which will integrate the IPPC approach in a consolidated version.^[8]) Waste management is a key element in preventing soil contamination. According to the EU waste hierarchy, waste should primarily be prevented and only secondarily reused, recycled, and recovered as much as feasible with landfills as the third option. (The new Waste Framework Directive will incorporate the content of the Hazardous Waste

Directive and the Waste Oils Directive.^[9]) The legal regime includes horizontal legislation on the waste framework, hazardous waste and the shipment of waste, directives dealing with waste installations, and those with specific waste streams.^[10]

Furthermore, EC chemicals law and water protection law prevent the entry of dangerous substances into the soil. With the new “REACH” system of registration, evaluation and authorization of chemicals, a comprehensive life cycle analysis, are to be carried out for highly soil-damaging harmful substances. The Nitrate Directive^[11] has caused limitations to the maximum amounts of nitrogen and contributed especially in endangered areas to a concentration reduction. Only plant protection products whose active substances are listed in the Pesticide Directive^[12] and do not pose a risk to the soils are authorized in the EU. With the Biocide Directive,^[13] a useful supplement is ensured for non-agricultural sectors. Because of the approach of the Water Framework Directive^[14] with its environmental quality standard of achieving a good ecological surface and groundwater status and its environmental action goal of implementing this condition within 15 years, the indirect aim of preventing pollutant concentrations in the soil has to be realized. Flood risk management policy also aims to reduce the impact of floods.^[15] Because of the inclusion of soil protection into the protection of special areas of conservation, the “Habitats Directive”^[16] forms the basis for a comprehensive consideration of all natural components of a habitat including the soil and contributes to the maintenance of soil biodiversity, especially because these community areas are such with often very sensitive soils.

EU air pollution control law^[17] aims to prevent the entry of various substances into the soil by an installation-related approach with pollutant-referred supplements. Member States can introduce stricter limit values at any time. The control of major accident hazards involving dangerous substances is ensured by the “Seveso II Directive,”^[18] which applies to some thousands industrial establishments where dangerous substances are present in high quantities. Also, general environmental provisions that have a strong procedural orientation and provide informative elements make a further contribution to a more conscious handling of the problems of soil protection. For example, the Environmental Impact Assessment Directive and the Strategic Environmental Assessment Directive^[19] are supporting instruments for the protection of the soils from harmful developments. The Environmental Liability Directive^[20] ensures that companies have to pay the costs for damages to the soils, only if they create a significant risk for human health. Moreover, research is needed to fill the gaps in soil knowledge and prepare for political and legislative action.

To sum up, the EU has already set up some standards in important fields of environmental law with direct or indirect effects on the soils, but a special soil protection policy

is in its infancy. Because of the threats to the soils in all EU Member States, an effective soil protection policy will have to be introduced.

INTERNATIONAL CONTEXT

International environmental policy is also far from achieving comprehensive soil protection. These problems in their entirety are not conceptually laid down by the law of international organizations in an obligatory form. In most cases, there is only “*pré-droit*” or “soft law,” e.g., in the World Soil Charter. Binding instruments in other fields of environmental policy might influence the use of the soils, especially the UN Convention to Combat Desertification (UNCCD), the Convention on Biological Diversity (CBD), and the UN Framework Convention on Climate Change (UNFCCC).^[21] Geographically relevant for the EU context, the achievements of the Council of Europe, which initiated international attention to the problems of soil protection by the adoption of the European Soil Charter already in 1972, go far beyond other regulations of international law, in particular by the decision on the “Revised European Charter for the protection and sustainable management of soil” on May 28, 2003. The idea of a international soil protection convention or at least a protocol to the CBD or the UNCCD, which would contribute to a more intensified dealing with the problems in all its facets, points in the right direction. A draft “Protocol for the Protection and Sustainable Use of Soil” as prepared by the Specialist Group of the IUCN Commission on Environmental Law is being discussed.

TOWARD A NEW EU SOIL PROTECTION FRAMEWORK DIRECTIVE

The Sixth Environmental Action Programme adopted on July 22, 2002 marks the beginning of an important phase of development with the intention to work on a specific “Thematic Strategy for Soil Protection” in the Community as a part of its plan to protect and preserve the natural resources. This strategy^[22] comprises a communication from the Commission and a legislative proposal that requires Member States to tackle the three priority threats of organic matter, i.e., decline, soil erosion, and soil contamination as well as the additional aspects of sealing, compaction, decrease of biodiversity, salinization, and floods and landslides. The EU institutions are discussing the proposed “Soil Protection Framework Directive,” which is not adopted. Several elements are being explored and assessed to decide whether to include them in the legislative instrument. The communication also identified the decline in soil biodiversity as a threat, but owing to the knowledge gap, it is not addressed in the directive proposal; closing this gap through research is regarded as an important aspect as well.

Among the elements being assessed and explored are the obligation to identify risk areas for erosion, organic matter decline, compaction, salinization, and landslides and the possibility of requiring Member States to establish programs of measures to combat the risks in those areas. The draft directive fills the gap between the classification and provisions required for the treatment of contaminated land that are completely missing in EU law yet and proposes setting a common definition of contaminated sites, a soil status report, and a common list of potentially soil-polluting activities that could be used by Member States to identify the contaminated sites on their territory and to establish a national remediation strategy. Moreover, preventive requirements are also being considered in the draft directive, e.g., to limit soil sealing.

There are many hurdles to face before the Soil Protection Framework Directive will be adopted. At least, it is clear that the legal base for soil protection provisions on EU level is Article 192 (1) of the Treaty on the Functioning of the European Union, which requires majority voting in the Council. In December 2007, EU Environment Ministers failed to find a compromise owing to the fear of administrative burdens for the Member States and the principle of subsidiarity under Article 5 (2) EU Treaty as a (false) counterargument. With respect to the strong local dimension of soils, action should mainly be taken on local level. But nevertheless there are reasons for EU-wide measures for soil protection, in particular the multifunctionality of soils, the transboundary consequences of, e.g., soil erosion and contamination, and the close correlation between soil degradation and other environmental problems (like climate change). Failure in protecting the soils will not only undermine sustainability, but also the long-term competitiveness of the EU.^[23]

In general, soil protection should be understood not only as minimization of damages, but also as comprehensive care and development of precautions and prevention of irreversible pollution and of harmful impacts on its functions.^[24] A mix of regulative and non-regulative instruments like in other fields of environmental policy would be appropriate for soil protection too. In the long term, the discussions within the EU institutions and in the Member States will hopefully pave the way for a policy that will ensure the protective and sustainable use of these natural resources.

CONCLUSION

The soil is a vital and largely non-renewable resource, and it has been subjected to several sector-related policy measures in the EU. The legislation covers some aspects of chemical and biological soil protection, but it is fragmented and achieves the aspect of safeguarding the soils

only as a side effect. Furthermore, EU law hardly takes any account of the requirements for the prevention of soil compaction, erosion, sealing, and other physical threats to the soil. This situation seems mainly due to the fact that EC legislation has not been orientated toward the different soil endangerment paths and the protection of the various soil functions. The proposed Soil Framework Directive tackles many of these critical aspects and develops instruments to solve the most severe problems. Agreeing on a international soil protection convention or at least a protocol to the existing UN conventions would also mean a great step forward. The need for the action in this field is particularly obvious and there are fundamental possibilities for improvement. In the course of these activities, we will hopefully have a genuine soil protection policy on EU level soon.

Abstract

The Kingdom Protista contains mainly unicellular eukaryotic organisms that cannot be classified into the three other kingdoms of plants, animals, and fungi. Protozoa are single-celled eukaryotic organisms commonly subdivided into four groups: flagellates, naked amoebae, shelled or testate amoebae (Testacea), and ciliates. Protozoa play a substantial part in energy and nutrient flows of terrestrial ecosystems. The impact of environmental and land management factors on protozoa results primarily from their effects on substrate supply and secondarily on soil structure, moisture, and climatic factors.

INTRODUCTION

The Kingdom Protista contains mainly unicellular eukaryotic organisms that cannot be classified into the three other kingdoms of plants, animals, and fungi. Protozoa are single-celled eukaryotic organisms^[1] commonly subdivided into four groups: flagellates, naked amoebae, shelled or testate amoebae (Testacea), and ciliates (Fig. 1). Naked amoebae are generally the most important group of protozoa in soil.^[2] Protozoa require a water film for locomotion and feeding, so their activity is limited to the water-filled pore space in soil. Most protozoa have adapted to fluctuating moisture by the ability to form resistant cysts, but ciliates require much higher soil moisture than flagellates or amoebae to be active.^[3,4] Reproduction is usually asexual by means of binary fission, but sexual reproduction also occurs.

IMPORTANCE IN SOIL, PLANT, AND ENVIRONMENTAL PROCESSES

Protozoa play a substantial part in energy and nutrient flows of terrestrial ecosystems, consuming 22% of the carbon (C) input to a beech-forest soil and 63% of the microbial biomass.^[5] Annual production is 39–98% of that of the total soil fauna,^[6] and their contribution to total net nitrogen mineralization in soil is 12–30%.^[7] Protozoa in soil systems regulate and modify microbial community activity and composition and inoculate new substrates with microorganisms.^[8,9] Their effects result mainly from their feeding activities because they are too small to directly influence soil structure. Soil protozoa are heterotrophic, feeding on bacteria, although mycophagous,^[10] predatory, and saprophytic protozoa occur.^[1] Approximately 40% of ingested nutrients are used for the production of protozoan biomass, while 60% are excreted.^[11] The effects of this nutrient turnover are such that the plants are significantly smaller and contain less nitrogen if protozoa are not present.^[2,8,9,11] Protozoa are a key

link in the terrestrial food chain as a major predator of bacteria and prey for larger organisms. The indirect effects of soil protozoa in stimulating plant growth are increasingly recognized and are probably more important than the direct nutritional effects.^[12]

FACTORS AFFECTING PROTOZOAN ACTIVITY AND COMPOSITION

The impact of environmental and land management factors on protozoa results primarily from their effects on substrate supply and secondarily on soil structure, moisture, and climatic factors. Protozoa decrease with soil depth, from approximately 10⁶/g at 10 cm to 10/g below 1 m, resulting from decreasing levels of organic matter down the soil profile.^[13] The application of organic manure to soil is an obvious source of added substrate and increases protozoan populations.^[14] Inorganic fertilizers also increase protozoan populations because of the increased plant growth, leading to a greater substrate input to the soil.^[14] The application of elemental sulfur, however, increased acidification of a Canadian pasture and reduced numbers of soil microorganisms and protozoa.^[15] Protozoa in soil are characterized by very rapid changes in density—amoebal numbers increase within two days of a rain due to a stimulation of bacterial prey.^[2] Seasonal maxima can be related to food supply, such as the spring and autumn peaks of *Dictyostelium mucoroides*^[16] and the peak of Testacea following autumn leaf fall.^[17] Population minima are typically related to unfavorable environmental conditions, such as dry summers and low temperature.^[13] Protozoa can rapidly encyst/excyst,^[18] such that 100% of the protozoa were active six days after watering a desert soil, compared to 0% before.^[19] Protozoa have a clumped horizontal distribution, again linked to substrate availability in the rhizosphere and in decomposing organic matter.^[20] Rhizosphere populations are, on average, sixfold higher than in

Fig. 1 Diagram of the four main groups of soil protozoa.

the surrounding soil.^[13] A 90-fold increase on decomposing grass residues in soil has been demonstrated.^[21] Protozoan species can be used as biological indicators of the environment.^[1] There were, e.g., marked differences in the species of testate amoebae among mor, acid-mull, and calcareous-mull litter types,^[22] and the ratio of *Colpodea* to *Polyhymenophora* is an indicator of soil disturbance.^[23] Soil protozoa are also used in laboratory bioassays to monitor pesticides and heavy metals.^[24]

METHODS OF STUDYING PROTOZOA

The study of protozoa in soil is hampered by their relatively small size, low numbers, and variable morphology. Direct enumeration has been most successfully used for testate amoebae^[25] and ciliates.^[26] Density-gradient centrifugation has enabled the direct observation of metabolically active protozoa.^[27] Culturing techniques rely on protozoan growth on laboratory media. A soil suspension is generally diluted using the most probable number technique,^[28] with modifications to allow the enumeration of mycophagous and active protozoa.^[10,29] Technological advances are being adapted to the study of protozoan populations in soil. Thus, a phospholipid fatty acid marker for protozoa has been identified,^[30] a β -N-acetyl-glucosaminidase-like enzyme has been identified as a putative marker for protozoan bacterivory,^[31] while molecular probes^[32] and analysis of 18S rRNA genes^[33] allow examination of protozoan communities without the need for culturing.

CONCLUSION

There is much we need to learn about this unknown and mostly unseen phylum and the many key roles its members have in the soil. Whether we like it or not, the protista are down there waiting, always in their thousands per gram soil—and for short but functionally important periods there will be millions of them.^[34]

Pyrite

Michael J. Borda

Department of Plant and Soil Sciences, University of Delaware, Newark, Delaware, U.S.A.

Abstract

Pyrite (iron disulfide, FeS_2) is both a geologically and an environmentally relevant mineral, and is ubiquitous in nature, with varied implications. Its occurrence ranges from hydrothermal systems, to metamorphic systems, to anoxic sedimentary systems. FeS_2 oxidation is known to be a cause of acid sulfate soils, acid mine and, rock drainage with significant environmental harm, in addition to being implicated as a key mineral in the origin of life and as a technologically relevant material. It is, by any account, an important earth material with a rich future in scientific research.

INTRODUCTION

Pyrite (iron disulfide, FeS_2) is a ubiquitous mineral, both temporally and spatially, in the geologic record. It is the most common disulfide mineral in nature and is associated with nearly every ore body type. FeS_2 occurs in metamorphic, igneous, and sedimentary rocks and is also found in extant-reducing environments, such as anoxic soils.

The name “pyrite” is derived from the ancient Greek word for fire, “pyros,” because of the generation of sparks when the mineral is struck. FeS_2 has historically been used for the production of chemicals and also as a material for jewelry manufacturing. Early in the American history, it was polished by Native Americans and used as mirrors. FeS_2 was of interest both as a means for producing sulfuric acid and as a source of iron. Sulfuric acid is generated through the controlled oxidation of FeS_2 by combustion in the presence of air. In the past, FeS_2 was regarded as a source of iron ore; however, it is only used in countries where oxide ores are unavailable. As new sources of sulfuric acid have been discovered and developed, the use of FeS_2 has dramatically decreased. It is mainly considered a nuisance material generated as a fraction of the waste rock during ore and coal mining operations, although there is some interest in FeS_2 for technological purposes because of its semiconducting properties.

MINERALOGY AND CRYSTAL CHEMISTRY

FeS_2 is isometric ($2/\text{m}^3$) and typically occurs as crystals of several different forms. Commonly, it is found in a cubic crystalline habit where pentagonal dodecahedral (pyritohedral) and octahedral forms have also been observed. FeS_2 is known to form framboids, or raspberry-shaped clusters, typically in sedimentary environments (Fig. 1). In the cubic form, faces are often striated because of oscillatory growth between cubic and pyritohedral

forms. FeS_2 is one of the two dimorphs with FeS_2 composition, the second being marcasite. Marcasite is typically formed at lower temperatures and, more characteristically, under lower pH conditions ($\text{pH} < 4.5$). A stability diagram for the S–Fe– H_2O system is shown in Fig. 2; however, marcasite is not shown because FeS_2 is a thermodynamically favorable species under the conditions represented.

FeS_2 is brittle and is unusually hard for a sulfide mineral ($H = 6\text{--}6.5$). It occurs as a pale brass yellow to yellow-white color, whereas specimens exposed to oxic conditions tend to look gray because of surface oxidation (tarnish). FeS_2 has a modified sodium chloride structure with iron at the sodium cubic corner and face-center sites and disulfide in the chlorine sites. Each iron atom in FeS_2 is octahedrally coordinated to six sulfur atoms, and each sulfur atom is tetrahedrally linked to one sulfur atom and three iron atoms (Fig. 3).

FeS_2 is a semiconductor, as defined by its relatively small band gap of 0.95 eV. The band gap is defined as the energy difference between the highest completely filled band (valence band) and the lowest completely unoccupied band (conduction band). The valence band of FeS_2 consists of iron 3d valence electrons and sulfur 3p valence electrons. Because of crystal field splitting, the iron d orbitals are separated into the lower-energy t_{2g} levels and the higher-energy e_g levels. The iron in FeS_2 is present as Fe^{2+} in a low-spin state where all 6d electrons are paired in the t_{2g} energy level. The sulfur in FeS_2 is present as S^{2-} , where two sulfurs make up the S_2^{2-} moiety.

OCCURRENCE

FeS_2 is the most common sulfide mineral and is found worldwide. Important localities occur in the United States, Spain, and Peru. FeS_2 forms over a range of temperatures, with the high-temperature forms being dominant in volume. One of the largest sources is massive sulfide

deposits associated with hydrothermal activity. In some high-temperature systems, such as epithermal veins (a hydrothermal mineral deposit formed within ~ 1 km of the earth's surface and in the temperature range of 50 – 200°C), the tendency is to form euhedral (i.e., having well-formed faces) crystals ranging in size up to 10 cm. The largest FeS_2 crystals are typically associated with metamorphism and can exceed 20 – 30 cm.

FORMATION

The formation of FeS_2 has been recognized to proceed via two possible mechanisms. One mechanism is the direct nucleation of FeS_2 from solution, whereas the second mechanism is through a replacement reaction generating

Fig. 2 A stability field diagram for the system $\text{Fe}^{2+}/\text{SO}_4^{2-}/\text{H}_2\text{O}$ where the activities of Fe^{2+} and SO_4^{2-} are set to 1×10^{-5} M. FeS_2 , hematite, and magnetite are the possible phases in the system, and the stability field of H_2O is shown for clarity.

Source: From Wyckoff Crystal Structures, 1969 (I), 346 (IV, g1).

FeS_2 from an iron monosulfide (FeS) precursor phase. The existence of euhedral crystals in hydrothermal systems has been one of the arguments for a direct precipitation mechanism. Experimental work has shown that the formation of FeS_2 through direct nucleation is insignificant compared with the formation via a FeS precursor.^[1] The source for sulfur species can be either hydrogen sulfide ($\text{H}_2\text{S}/\text{HS}^-$), thiosulfate, or polythionate species. This adds an important constraint on systems where FeS_2 is forming. FeS species are far more soluble and allow higher concentrations of iron and sulfur to be concentrated in systems before monosulfide formation occurs. Once the precursor FeS is formed, FeS_2 formation is facile and can produce macroscopic crystals.

An important texture of FeS_2 typically associated with soil environments and ore deposits is the framboidal form. Framboids are spherical structures composed of a number of microcrystals. The formation mechanism for framboidal FeS_2 is thought to proceed through a precursor phase, called greigite. However, some experimental works have shown that this phase is not a prerequisite, and framboidal FeS_2 can form through the reaction of amorphous FeS and H_2S .^[2]

REACTIVITY

The reactivity of FeS_2 , namely the oxidation reaction to form sulfuric acid and iron oxides, is a significant environmental concern. This process generates acid sulfate soils,

acid mine drainage, and non-anthropogenic acid rock drainage and may have harmful consequences for the entire watersheds that are affected. The oxidation of FeS_2 commonly proceeds because of the drainage of anoxic soils and sediments or through the excavation of pyritic materials during mining and subsequent exposure to aerobic surface conditions. Two main oxidants are important: molecular oxygen and ferric iron (Fe^{3+}); however, often overlooked is the significance of water. The reaction is catalyzed by bacteria (*Acidithiobacillus ferrooxidans*) through the oxidation of Fe^{2+} (product) back to Fe^{3+} (reactant). The products of oxidation reactions cause the acidification of streams draining the area affected and can result in the mobilization and transport of associated heavy metals. This ultimately has resulted in a \$1,000,000 per day environmental problem in the United States alone.^[3]

IMPLICATIONS

From an environmental standpoint, FeS_2 is a material that must be understood to develop abatement strategies to halt the acidification process. FeS_2 is a promising photocatalyst for environmental contaminant degradation and has also played a critical role in other fields. In the late 1980s, a hypothesis that the formation of FeS_2 may be the driving force for the chemoautotrophic (bacteria that fix carbon dioxide to make their own food source using fuel from chemical reactions) origin of life was proposed.^[4] FeS_2 has also been implicated as being a source of hydrogen peroxide on an early, anoxic earth, possibly playing a role in the evolution of oxygenic photosynthetic organisms.^[5] Along with its importance to the earth history, FeS_2 is also a technologically important material. Because of its semiconducting properties, FeS_2 is important to photoelectrochemistry and photocatalysis.

CONCLUSION

FeS_2 is both a geologically and an environmentally relevant mineral, and is ubiquitous in nature, with varied

implications. Its occurrence ranges from hydrothermal systems, to metamorphic systems, to anoxic sedimentary systems. FeS_2 oxidation is known to be a cause of acid sulfate soils acid mine/rock drainage with significant environmental harm, in addition to being implicated as a key mineral in the origin of life and as a technologically relevant material. It is, by any account, an important earth material with a rich future in scientific research.

ACKNOWLEDGMENTS

I would like to thank Dr. Martin A. Schoonen at Stony Brook University for giving me the opportunity to work on such a wonderful mineral and for the support and encouragement. I thank Alexander Smirnov for constructing the figures for this entry. I also thank Jerry Bigham for an excellent and constructive review and Rattan Lal for the opportunity to write this entry.

Pyrogenic Carbon

Barry G. Rawlins

British Geological Survey, Nottingham, U.K.

Abstract

This entry describes the range of substances in the soil that are encompassed by the term “pyrogenic carbon” (PyC). The two main processes for its generation are wildfire and purposeful charcoal/biochar production. It describes how it is quantified and characterized, with reference to further methodological advances. The impact of PyC on soil properties and the occurrence of PyC in soils in global ecosystems are described. The potential importance of PyC for climate change are presented, identifying a series of key knowledge gaps relating to PyC. It concludes by commenting on the paucity of research undertaken on PyC in the soil and identify the focus of such research in the forthcoming years.

INTRODUCTION

Substances referred to as pyrogenic carbon (PyC) are generally considered to form a continuum from charred plant materials, through charcoal, with an end point of graphite. Its common characteristic is an abundance of condensed aromatic ring structures and—when generated under higher temperatures—larger graphene sheets (Fig. 1). PyC is created naturally by wildfire and the combustion of fossil fuels and has been created by man for centuries as what is commonly referred to as charcoal. Interest in PyC has increased because of the need to better understand the global carbon (C) cycle and its potential role in enhancing C sequestration in the biosphere due to its greater chemical recalcitrance when compared with more common, labile soil C compounds, with implications for climate change.^[1] The term “pyrogenic carbon” that has been used in the soil science literature since around the year 2000 includes materials commonly referred to as black carbon (BC), elemental C, and biochar. The latter term has been used since around 2007 to refer to the purposeful charring of biomass with the intention that it is applied to soil to improve fertility, C storage, and filtration of percolating water.

GENERATION OF PyC

Two types of PyC are typically generated—soot condensates and solid residues. Soot comprises small molecules released by pyrolysis and recombination by free radical reactions. Solid residues of PyC form largely during the smoldering phases of combustion where fuel gases produced by pyrolytic (oxygen-depleted) reactions are insufficient to maintain a flame. Wildfire temperatures leading to the formation of PyC typically vary between 200°C and 500°C while ancient societal practices of charcoal production have been adapted using modern technology to

generate PyC (charcoal/biochar) residues on both local and industrial scales.^[2]

Measurement and Characterization

The chemical compositions of PyC and the terms used to define its components are shown in the van Krevelen diagram (Fig. 2). Methodologies have been developed to discriminate the BC component of PyC from two other forms of C in the soil: inorganic C and unaltered organic C from the decomposition products of plant materials. The first step in many methods for quantifying the BC in soil is the removal of inorganic C by pretreatment with hydrochloric acid. Many approaches for quantifying BC in soil use a variety of means to oxidize the unaltered soil C including heating, acids, or photooxidation followed by analysis of the residue for C. An alternative approach is the use of molecular markers such as benzene polycarboxylic acids. Further details of these and other approaches were discussed in greater detail.^[3] Methods that can provide more detail of PyC material along its continuum are being developed^[4] based on measuring the degree of aromatic condensation. Broad chemical characterization of PyC is also often undertaken by analysis with ¹³C nuclear magnetic resonance spectroscopy.

Influence on the Soil

PyC has several important characteristics that influence the properties of soils when it occurs in reasonable quantities. First, it is more recalcitrant than thermally unaltered soil C and so persists in soil for longer periods; because of its chemical composition, it is resistant to microbial decay and degrades slowly by abiotic processes. Numerous studies have attempted to estimate the longevity of PyC in soil; these range from a few decades to several thousand years depending on soil conditions.^[5] Second, it has a very large

Fig. 1 Model of a PyC particle in soil comprising both crystalline graphene sheets surrounded by amorphous aromatic structures, with a range of pore sizes.

Source: Reproduced with permission of Earthscan Ltd., www.earthscan.co.uk.

surface area (ranges from 50 to 400 m² g⁻¹) due to its highly porous structure. This can markedly increase the water-holding capacity of the soil. After incorporation into the soil, the charged surfaces of PyC from the formation of functional groups contribute to progressively increasing soil cation-exchange capacities, improving fertility in agricultural soil. Some studies have suggested that greenhouse gas emissions

of nitrous oxide and methane decline when PyC has been applied to the soil.^[6] The charged surfaces of PyC enhance sorption with clay mineral surfaces (Fig. 3), leading to increased aggregation and improved soil structural characteristics. PyC is known to have a significant impact on mycorrhizal fungi in soil where they form intimate associations. Mechanisms through which PyC influence mycorrhiza in soil include the alteration of soil physical and chemical properties (fine pores providing a refuge), indirect effects through impacts on other soil microbes, and changing

Fig. 2 van Krevelen plot of molar ratios for biomass and pyrogenic materials.

Fig. 3 Scanning electron micrographic image of a PyC particle in the soil with a coating of clay minerals determined by energy dispersive X-ray analysis.

plant–fungus signaling;^[7] however, there is little understanding of the relative importance of these mechanisms.

Occurrence of PyC in Soil

The quantity of PyC in soils generated by wildfire is related to the ecosystem type; the proportions of PyC in relation to total soil organic carbon (SOC) for forested and non-forested ecosystems have been summarized.^[8] For example, PyC comprises up to 33% of SOC in Japanese grasslands subject to frequent burning and up to 82% in the topsoils in parts of Australia.^[9] Where PyC has been generated by man and applied to the land forming the terra preta soils of the South America, PyC comprises up to 20% of SOC. Studies have suggested that physical breakdown of PyC residues results in particles with sizes finer than 50 μm .

Impacts on Climate Change

Greater understanding on the quantities and forms of PyC in soil has the potential to improve our understanding of feedbacks between projections of climate change and terrestrial ecosystems, including emission of carbon dioxide (CO_2) from the soil. A further study demonstrated that by incorporating accurate stocks of BC in climate prediction models, CO_2 emissions were reduced by 18.3% and 24.4% in two Australian savannah regions in response to a warming of 3°C over 100 years.^[9] In the case of biochar production of PyC and its purposeful incorporation into the soil, estimates have been made of the scale this contribution could make to terrestrial C sequestration. By adopting slash-and-char policies at a global scale, rather than slash-and-burn that releases all C to the atmosphere, 0.21 peta grams of carbon (PgC) could be sequestered in the soil each year. Using all agricultural, forestry, and urban wastes to create biochar and applying it to soil could sequester 0.16 PgC yr^{-1} , while if a proportion of renewable energy demand was met through pyrolysis, the figure increases substantially to 5.4 PgC yr^{-1} .^[10]

Knowledge Gaps

In areas prone to wildfire and managed burning, few data are available on the pools and fluxes of PyC, specifically that proportion converted into solid PyC and soot PyC. In terms of the C cycle, the fate of PyC residues is unknown—is it subsequently consumed by fire or oxidized, and if so at what rate? There is a lack of quantitative data on PyC storage in boreal peatlands. Losses of PyC to the atmosphere need to be tracked and its fate determined.

As a means of increasing soil C sequestration, some advocate vastly increasing the generation of biochar (PyC) and its application to soil yielding agronomic benefits. Despite the potential positive features of biochar, others are more cautious suggesting that little is known of its long-term impacts on soil properties and functions. In particular,

there are many outstanding questions concerning the impact of PyC on soil microbial communities, its long-term stability and dynamics in soil, its impact on the links between the C and nitrogen cycles (where models need to be developed), and its erosion, transport, and fate.

CONCLUSION

Despite the potential importance of PyC in the global C cycle and its implications for understanding the magnitude of climate change due largely to rising atmospheric CO_2 concentrations, remarkably little research has been undertaken on the biogeochemical cycle of soil PyC. Much of the research on characterization, impacts on soil properties, and fate will likely stem from the further increase in biochar-related research. Methods for characterizing PyC are likely to improve measurement along its continuum and aid understanding of how pyrolysis temperatures, duration, and feedstock influence its behavior and properties in the soil. This should enable a more thorough system for the classification of PyC substances in the soil and aid modeling of its turnover.

Quality

Ed G. Gregorich

*Eastern Cereal and Oilseed Research Centre, Agriculture and Agri-Food Canada,
Ottawa, Ontario, Canada*

Abstract

Depending on the use, soil quality may mean different things to different people. For example, in the agricultural context, within which much of the discussion of soil quality has taken place, the farmer may think of soil quality in terms of productive land that maintains or increases farm profitability, as well as the conservation of farm resources so that future farming generations can make a living. To the consumer, agricultural soil quality may mean a dependable supply of wholesome, affordable food and the protection of drinking water quality. To the environmentalist, it may be defined in terms of global nutrient cycling, water regulation, climate change, and biodiversity. And for high-level policy and decision makers, soil quality may be seen in terms of a nation's ability to stay competitive in the international marketplace and to honor its international environmental commitments.

INTRODUCTION

Concisely defined, soil quality is the degree of fitness of a soil for a specific use—its ability or capacity to function for a specific purpose.^[1,2]

BASIC SOIL FUNCTIONS

Soil performs six main functions: sustaining plant and animal life, regulating water, regulating gases, regulating energy, buffering against or filtering out potential environmental contaminants, and providing physical support for human structures such as buildings and roads. How well a soil carries out these functions determines its quality.

INHERENT AND DYNAMIC SOIL QUALITY

Soil quality has both an inherent or natural element determined by geological materials and soil formation processes (such as chemical and physical weathering and a dynamic element determined by management practices). Natural processes, such as erosion and the subsequent loss of organic matter, compaction, and salinization can degrade the inherent quality of soil. Human activity, such as agriculture, can accelerate these processes through various land use and management practices, hastening the symptoms and effects of soil degradation. On the other hand, some agricultural land uses and practices (such as various tillage methods, cropping systems, and nutrient management plans) help to stabilize or improve soil quality.

SUSTAINABLE DEVELOPMENT

The interest in soil quality is linked to sustainable development. A soil management system is considered sustainable only if it maintains or improves soil quality and does not compromise environmental quality beyond a degree acceptable to society. Only by understanding soil quality and promoting it can we achieve environmental protection and preserve soils in a usable state for future generations. Regular monitoring of soil quality allows land managers to assess the sustainability of various land uses and management practices.

DEVELOPING A FRAMEWORK TO ASSESS SOIL QUALITY

Soils are the interface between terrestrial ecosystems and both aquatic ecosystems and the atmosphere. Based on the linkages between ecosystems, soil quality is normally defined using environmental and economic performance criteria, including those of plant and animal health and productivity. Soil quality and soil health are often considered synonymous, but some researchers make a distinction between these terms by considering soil health as a subset of soil quality and by stressing that the focus of soil health is on the organic and more dynamic soil properties. This latter concept expands to a larger view of soils as a key component for sustainably supporting all terrestrial ecosystems.

A useful framework for assessing soil quality begins with a description of the functions on which such quality is to be based (i.e., those most likely to influence the performance criteria). For example, at the ecosystem or

global scale, soil functions include regulating both biotic processes (e.g., supplying plants with mineral nutrients and water) and the flux of elements [e.g., the turnover and storage of carbon (C), nitrogen, phosphorus, and sulphur]; mitigating the accumulation of greenhouse gases [e.g., carbon dioxide (CO₂), NO_x, and methane (CH₄)]; altering the chemical composition of precipitation and distributing water throughout the environment; contributing to the gas, water, and heat balance of the atmosphere; and serving as a biological habitat and genetic reserve.^[3,4]

Once soil functions are known, soil characteristics or properties that support these functions, along with important interactions of these characteristics, must be identified.^[5] Much of the work to characterize soil quality has been carried out for agricultural soils. Table 1 lists some of the physical, chemical, and biological characteristics and processes of agricultural soils that contribute to the soil quality functions that support agricultural productivity and sustainability.

Table 1 Some soil quality functions that are important for crop production.

Soil quality functions	Function characteristics and processes involved
Support plant growth	Provide suitable medium for seed germination and root growth
Show absence of adverse chemical conditions (e.g., acidity, salinity, sodicity)	
Supply balance of nutrients	
Provide suitable medium for microorganisms (for decomposition, nutrient cycling)	
Promote root growth and development	
Regulate water	Receive, store, and release water for plant use
Retain water adequately to buffer and reduce effects of drought	
Provide adequate infiltration and storage capacity to reduce runoff	
Regulate gases	Accept, hold, and release gases
Have conditions for adequate air exchange with atmosphere	
Regulate energy	Store energy-rich organic matter
Decompose, mineralize, and recycle nutrients and energy	
Buffer or filter	Accept, hold, and release nutrients
Sequester biotoxic elements

EVALUATING SOIL QUALITY

It is not feasible or even practical to measure all soil properties in order to assess the soil quality. Soil quality indicators are needed that encompass the whole range of physical, chemical, and physical properties of the soil; reflect soil function; are easy to measure for a variety of users and under various field conditions; and respond to changes in climate and management. The concepts underlying the criteria to select key indicators of soil quality, along with the interpretative framework needed to link the response of the measured indicator to management action and the issue of concern, are described in another section of the encyclopedia. Assessment of the indicators is critical in determining whether a soil process is unrestricted or a soil is fit for use. The approaches used to set quantitative critical limits or ranges of soil indicators, which help determine whether the value of the indicator adequately describes soil performance, are discussed in another section of the encyclopedia.

Land management practices used in agricultural production usually result in a degradation of the structures, or a perturbation of the processes, that help to maintain natural ecosystems in equilibrium. The inherent and dynamic aspects of soil quality that help accurately assess sustainable crop and animal production, and the link between soil quality and development of sustainable management systems (i.e., those that foster reduction in the inputs of non-renewable resources, maintain acceptable levels of productivity, and minimize impact on the environment) is described in other sections of the encyclopedia.

The framework used to interpret and assess soil quality must also be useful in evaluating effects in adjacent areas or systems. A description of soil properties important to the process of erosion and the consequences of erosion on soil functions, the relationship between soil quality and the quality of receiving waters, and the effects of both soil management and soil quality on the soil processes that produce and consume carbon and nitrogen gases are discussed other sections of the encyclopedia.

MONITORING SOIL QUALITY

In natural systems, soil quality is observed as a baseline value or set of values against that future changes in the system can be analyzed and compared. In agricultural systems, soil quality is monitored with the view toward managing the system to enhance production while not degrading soils and the environment.

The selection and quantification of properties used to assess soil quality are often based on their spatial and temporal variability, on whether they are desirable for crop production, and on whether they can be controlled or managed in a time frame relevant for annual crop production (i.e., relatively short-term) or for long-term sustainability.^[6] A set of basic soil properties and characteristics has been

Table 2 Some soil physical, chemical, and biological properties used as indicators of soil quality.

Soil property	Method	Information
Physical properties		
Soil texture	Hydrometer method	Retention and transport of water, nutrients, and chemicals; susceptibility to erosion; stabilization of organic matter and soil structure
Topsoil and rooting depth	Soil coring, excavation	Water and nutrient availability, rooting volume for crop production
Soil bulk density	Soil core, neutron probe	Volume of pore space, compaction
Infiltration, hydraulic conductivity	Pressure, tension infiltrometer; permeameter; laboratory measurement on cores	Runoff and leaching potential, drainage
Water content	Gravimetric measurement by oven drying; volumetric measurement by time domain reflectometry or core	Available water
Water release curve, water-holding capacity	Water content at 33 and 1500 kPa tension	Availability of air and water, retention and transport of water and chemicals, drainage
Chemical properties		
pH	pH meter	Acidity or alkalinity of soil, nutrient availability
Electrical conductivity	Conductivity meter	Presence and quantity of soluble salts
Available N, P, and K	Laboratory extraction and analysis	Plant available nutrients
Organic C and N	Wet or dry combustion	Organic matter reserves, nutrient cycling, soil structure
Biological properties		
Potentially mineralizable N	Aerobic or anaerobic incubation	Potential to supply plant-available N
Microbial biomass	Chloroform fumigation followed by incubation or extraction	Size of microbiological population, pool of rapidly cycling organic matter and nutrients
Soil respiration	<i>In situ</i> and laboratory measurements by CO ₂ gas analyzer or alkali traps	Availability of soil organic matter reserves, microbiological activity

Source: Adapted from Doran & Parkin.^[7]

proposed as indicators of soil quality.^[7] Table 2 lists a set of indicators that forms the core of most data sets used to characterize soil quality. From this data set, it is possible to derive other relevant indicators such as available water, microbial quotient, and respiratory quotient. It has been proposed that a suitable level of precision for soil quality indicators is the ability to detect a 10% change at the 90% confidence level.^[8]

Some indicators are less useful than others because of high temporal and/or spatial variability, because of strong correlation to other indicators, or because the response of the indicators to change is not readily interpreted.^[8] Selecting an appropriate suite of indicators or adopting surrogate indicators for a particular soil quality assessment is an important first step in monitoring soil quality, and there is a need to balance the cost of measuring particular indicators against the value of the information obtained.

Statistical quality control methods have been proposed to determine the range of variation and to set control limits for properties^[9] in order to provide the farmer with information to manage the soil in a sustainable manner. The theory behind these methods is that if upper and lower control limits, based on known or desired tolerances, can be established to represent minimum levels for sustainable

Table 3 Soil properties that can be estimated from input variables using pedotransfer functions.

Soil property	Basic input variable ^a
Cation exchange capacity	Clay type and quantity + organic carbon
Water retention characteristic; hydraulic conductivity; volumetric water content	% Sand, silt, clay + organic carbon + bulk density
Aerobic and anaerobic microbial activity	Water-filled pore space (calculated from bulk density, particle density, and water content)
Soil strength	Bulk density and water content
Rooting depth	Bulk density, water-holding capacity, pH, electrical conductivity
Leaching potential	% Sand, silt, and clay; pH; organic carbon; hydraulic conductivity, cation exchange capacity; depth

^aVariable used in pedotransfer function.

production, then changes in critical parameters can be identified and corrective action taken to adjust the management system.

When data are unavailable, pedotransfer functions can be used to estimate values of soil characteristics^[10,11] (Table 3). Pedotransfer functions are functional relationships (i.e., regression models) that transfer known soil properties (e.g., texture, bulk density, organic C content) into unknown soil properties (e.g., soil hydraulic conductivity, volumetric water content). The main advantage of pedotransfer functions is that they are relatively inexpensive and easy to derive and use. The disadvantage of these functions is that some may not be appropriate for application at a specific site and should not be used to make predictions for soils that are outside the range of soils that were used to derive the pedotransfer functions originally.

Quality Index: Soil

Toru Nakajima

Department of Agriculture, Meiji University, Kawasaki, Japan

Abstract

Soil quality index (SQI) assessment has become an internationally accepted science-based tool for advancing the assessment, education, and understanding of soil resources. Soil quality is most often defined as the capacity of soil to function within ecosystem and land use boundaries to sustain productivity, maintain environmental quality, and promote plant growth as well as animal health. SQI assessment requires an evaluation of physical, chemical, and biological attributes to know how well the resource is functioning. Therefore, SQI seeks to characterize the overall agro-ecological functions of soil by selecting soil physical, chemical, and biological properties as indicators, measuring them, and calculating a score or index for both the individual properties and overall soil quality. There are three basic approaches for evaluating the sustainability of agricultural management: 1) comparing different management systems; 2) comparing the same site over time and finding trends; 3) comparing with problem and non-problem areas. Numerous investigators have proposed conceptual frameworks and models to evaluate soil quality including the scoring function analysis. SQI systems approach is needed to integrate the knowledge of soil science into solutions for natural resource problems.

INTRODUCTION

Soil quality indexes (SQIs) have been recognized as assessing tools for land use and soil management practices worldwide.^[1] The soil quality is important not only for the production of food and fiber but also in the maintenance of local, regional, and worldwide environmental quality.^[2] Soil quality is most often defined as the capacity of soil to function within ecosystem and land use boundaries to sustain productivity, maintain environmental quality, and promote plant growth as well as animal health.^[2] The SQI has to reflect the soil physical, chemical, and biological properties and processes and interactions within each soil resource and their interactions within each soil.^[3] Furthermore, SQI can be used to monitor trends in soil properties and functions over time to determine if soil quality under different land use and management is aggrading, sustaining, or degrading soil attributes.^[4] However, there is no universal method or tool to assess soil quality, although investigators have proposed conceptual frameworks and models to evaluate soil quality.^[5–10]

CONCEPT OF SOIL QUALITY ASSESSMENT

Assessing soil quality can help in understanding the emphasis on sustainable land use with a holistic focus emphasizing on sustainable soil managements (e.g., soil erosion tolerance and resiliency of crop products), and the concept has two aspects for education and assessment.^[4] Soil quality assessment and education may provide a better

understanding and awareness for essential ecosystem services.

There are three basic approaches for evaluating the sustainability of agricultural management: 1) comparing different management systems for differences in soil quality; 2) comparing the same site over time and finding trends; and 3) comparing within the areas with problem and non-problem.^[9] The second approach includes assessing changes in the soil properties over time to identify the trends.^[11] To find the trends, establishing baseline values for the various soil properties and monitoring changes of those properties are required. When SQI has positive trend, it indicates that soil is improving or aggrading in soil quality.^[9] Contrary, when SQI has negative trends, then soil is degrading. In addition, a flat trend could indicate sustainable. The processes include establishing criteria and condition to guide the evaluation processes, such as establishing ranges for indicator values that are appropriate for the specific soils, and determining the relative importance or weight that should be given to each indicators.^[9] This indexing soil quality assessment is an important step. It involves selecting appropriate soil quality indicators to efficiently and effectively monitor critical soil functions as determined by specific management goals.

SQI METHOD

Numerous investigators have proposed conceptual frameworks and models to evaluate soil quality.^[5–10] For instance, when calculating a soil quality index (SQI), linear

Fig. 1 Conceptual framework for scoring function analysis.

Source: Adapted from Andrews, Karlen, et al.^[5] ©2004 Soil Science Society of America.

and multiple regression analysis,^[12] pedotransfer functions analysis,^[13] principal component analysis (PCA),^[6,10] and scoring function analysis^[14] have been used. This entry describes one of the common methods termed “scoring function analysis” for SQI assessment.

The scoring function analysis for SQI assessment has three main steps, as followed by Andrews and Karlen: 1) identification of the minimum data set of indicators; 2) indicator interpretation; and 3) integration of the all indicator scores into one overall SQI value^[5] (Fig. 1). For the first step, SQI indicators are selected for soil physical, chemical, and biological properties according to the appropriate indicator for the management goal in the study. Doran and Parkin^[2] stated the importance of selecting appropriate indicators that could be measured which influence the capacity of a soil to perform and also be sensitive to the final outcome. In the second step, each indicator from the minimum data set is transformed into unit less combinable score ranging from 0 to 1 (where 1 represents the high level for indicators and contrary 0 represents the low level for indicator). There is a criterion for transforming indicators to scores for accounting their contribution to soil functions. In general, there are three general shapes of standard scoring function for SQI.^[8,15] Increasing the level of the indicators when the quality of the soil is increasing, “the more is better” curve is used. Conversely, “the less is better” curve is suitable for decreasing the level of the indicators by increasing the quality of soil. In addition, “the optimum” curve scores those indicators that have an increasingly positive association with soil quality up to an optimal level beyond which quality of soil decreases^[6] (Fig. 1). After considering the appropriate curve type for indicators, a scoring of functions chart for interpretation of SQI is created.

The third step, the score values (e.g., ranging from 0 to 1) of each soil indicators are given specific weights based on their contribution to management goal. The individual

scores are multiplied by weighting factors and combined by addition into an overall SQI (Fig. 1). The weightings were given subjectively; nevertheless, the soil physical, chemical, and biological properties are given almost equal weighting to emphasize the equal importance of these three categories of soil properties in their contribution to soil functions.

SOIL PHYSICAL, CHEMICAL, AND BIOLOGICAL INDEX FOR SQI

Research on soil quality assessment has focused on indicator selection and evaluation and minimum data set for SQI.^[4] Numerous researches are being conducted to describe accuracy, sensitivity, and contribution of various soil properties and processes. The indicators for SQI assessment must be evaluated based on multiple physical, chemical, and biological properties and their interactions. One aspect of indicator research to select the minimum data set is science-based statistical skill (e.g., PCA and pedotransfer function analysis) to select the suitable indicators. Larson and Pierce^[16] reported that pedotransfer analysis and potential soil indicators include: 1) bulk density; 2) water retention; 3) saturated hydraulic conductivity; 4) porosity; 5) random roughness; 6) soil productivity; 7) root depth; 8) cation exchange capacity; 9) soil organic carbon; and 10) phosphate sorption capacity.^[16] It is needed to be understood how soil properties and processes interact within ecosystems.^[7]

SUMMARY

The SQI assessment has become an internationally accepted science-based tool for advancing the assessment, education, and understating of soil resources.^[4] The SQI has to reflect the soil physical, chemical, and biological properties and processes and interactions within each soil resource. There are three basic approaches for evaluating the sustainability of agricultural management: 1) comparing different management systems; 2) comparing the same site over time and finding trends; 3) comparing with problem and non-problem areas. Numerous investigators have proposed conceptual frameworks and models to evaluate soil quality including the scoring function analysis. SQI systems approach is needed to integrate the knowledge of soil science into solutions for natural resource problems.

Quality: Assessment by Interpolation Techniques

Vincent Obade

School of Environment and Natural Resources, Ohio State University,
Columbus, Ohio, U.S.A.

Abstract

Environmental hazards such as pollution, flooding, and other repercussions linked to abrupt climate change cause social and economic hardships and are exacerbated by soil degradation. Thus, detailed and accurate soil quality status maps in digital and analog format are required to identify soils susceptible to degradation. This entry explains the scientific basis of soil quality interpolation and mapping and techniques of assessment. Indeed, the accurate determination of soil quality is constrained with problems that range from data availability to the requirement of complex models to capture the spatial heterogeneity of soil properties. Thus, the integration of different approaches and tools to handle data scarcity and minimize errors to generate simplified soil quality maps is discussed.

INTRODUCTION

The 21st century is faced with challenges caused by the spiraling population increase and demand for food, energy, and water; indiscriminate land use conversions; and the catastrophic impacts of abrupt climate change partially attributed to soil degradation.^[1] Addressing these challenges necessitate concrete availability of scientifically credible information backed by proactive and strategically targeted management. The judicious management of soil resources holds the key to sustainability of earth's resources and thus socioeconomic viability.^[2] Thus, models that synthesize soil property information into simplified formats can play a critical role in the conceptual understanding of soil systems and the identification of key sustainable practices. Soil quality is defined as the capacity of the soil to support ecosystem functions such as nutrient cycling and water purification and encompasses the fitness of the soil for specific uses (e.g., road construction and agricultural production).^[3]

Soil quality can be determined qualitatively (e.g., visually where darker soils are considered to have a high organic matter, thus of high quality) or quantitatively by measuring the soil physical, chemical, and biological properties (Table 1). Soil biological properties are indirectly inferred from other soil properties [e.g., soil organic carbon (SOC)], because of 1) inaccuracies in earthworm counts (i.e., by hand); 2) difficulty in accounting microbial species diversity; and 3) difficulty in interpreting the soil respiration tests. The SOC, a proxy of soil quality, influences the soil ecosystem functions and productivity.^[4] High SOC reduces risks of eutrophication from agricultural runoff laden with nitrate (NO₃) or pesticide leaching. Stocks of SOC are computed by multiplying the SOC content (%) with the dry bulk density (ρ_b), for each soil layer, minus the fraction of fragments >2 mm or by the use of pedotransfer functions (PTFs).

Characterizing soil quality is challenging because of the landscape spatial heterogeneity and the fuzzy definition of soil quality. Despite numerous challenges, the laboratory determination of soil quality has its own problems. For example, the determination of SOC, by chromate oxidation or “wet combustion” method, produces toxic wastes that must be properly disposed and is inaccurate because of the incomplete oxidation of soil organic matter, whereas the dry combustion is expensive and slow. Another technique, loss on ignition, though relatively cost-effective, is inaccurate because certain mineral fractions are also decomposed when heating to the high temperatures required by this method.^[5] Laboratory methods can be prohibitively expensive, when the number of samples to be analyzed is large.

Advances in automation, digital computation, or machine learning have ignited new prospects for characterizing and mapping complex features.^[6] Maps describe earth surface features, either on hard copy or digitally. Digital soil mapping entails the “computer-assisted” production of digital representations of soil type or soil properties, over a spatial domain.^[6] Machine learning methods interpolate and make predictions based on spatially exhaustive environmental variables and are therefore useful for enumerating the inter-relationship between soil properties and other covariates; a practical example being the *scorpan* paradigm^[7] that comprises the following: 1) s: soil, other or previously measured attributes of the soil at a point; 2) c: climate, climatic properties of the environment at a point; 3) o: organisms, including land cover and natural vegetation; 4) r: topography, including terrain attributes and classes (e.g., slope, aspect, area, and direction); 5) p: parent material, including lithology; 6) a: age, the time factor; and 7) n: space, spatial or geographic position.

Generally, indicators need to be prioritized, ranked, or weighed based on importance or effectiveness in

Table 1 Soil quality assessment methods.

Qualitative (e.g., by visual observation)	Quantitative
Soil color: (i.e., darker soils perceived to be of relatively higher quality)	Soil physical, chemical, and biological properties (e.g., SOC, texture, ρ_b , water-holding capacity, pH, aggregate stability, electrical conductivity, earthworm count, and soil depth; http://soilquality.org/indicators.html)
Soil tilth: (good-quality soils have clods easily broken on tillage)	Soil erosion, pollution
Compaction (good-quality soils have no hard pan and have little resistance to plough on tillage; http://pubs.cas.psu.edu/FreePubs/pdfs/uc170.pdf)	Soil tensile strength/stability for construction or civil works
Water infiltration and drainage (e.g., good-quality soils drain well, compared with poor-quality soils that exhibit slaking and surface sealing, reduced water infiltration, and increased runoff and erosion)	Agricultural productivity (i.e., yields)
Hybrid methods: USDA Soil Quality Test Kit and Interpretive Guide; Cornell Soil Health Testing (http://soilhealth.cals.cornell.edu/).	Mathematical and statistical models (e.g., GIS, PTFs, and other regression models)

accomplishing or measuring selected tasks. The simpler or less detailed the indicator, the easier to identify, model, understand, and address the specific concerns that may include evaluating management efficacy or policy intervention. Geographical information system (GIS) generates maps from overlays of different data sets that can be used for prioritizing during decision-making and for evaluating alternative strategies. However, GIS is no panacea and has its own challenges. For example, the data used in overlays are derived from multiple sources, in different formats, time spans, and resolutions. Therefore, it is challenging to merge or standardize these data sets. Furthermore, mapping accuracy varies with the level of detail and generalization. Thus, it should not be construed that measurements made on the paper or digital map products reflect the exact location of all these features on the ground.

Thus, science-based techniques are required for establishing the least amount of data from an entire data set that mimic changes in soil quality vis-à-vis land management or geographic location. Due to the uncertainty with regard to soil quality benchmark selection, soil quality status may preferentially be determined on a relative basis. To date, there is no universal equation or soil quality prediction model that fits all ecoregions. Furthermore, different measurement and modeling techniques have different assumptions, which may create errors, exacerbating problems of interpretation and hampering efforts toward the judicious management of agroecosystems. However, it should be envisaged that measurements integrated with theories, hypotheses, or models can lead to discovery or insights on earth processes. Therefore, this entry expounds on the conceptual framework (Fig. 1) for interpolation and mapping of soil quality, limitations, and future research prospects.

**Fig. 1** Compartmentalized framework of soil quality spatial interpolation and mapping.

FRAMEWORK FOR SPATIAL INTERPOLATION

Sampling

Sampling entails the selection of a subset of data or observations to estimate the characteristics of the whole data set or to predict values at unsampled locations.^[8] Selecting a suitable sampling design can reduce analysis costs and time, enhance precision, and support repeatability in experiments. Examples of sampling designs include the simple random sampling (SRS), stratified random sampling, and systematic random sampling. The SRS considered as the reference method, selects calibration sites at random with all sites having the same probability of being sampled, and has no restrictions on their spatial locations. Although SRS is a simple method, some domains of the distribution and modalities of parameters may be missing or large gaps may occur in the sample. Alternately, stratified methods generate a set of samples that more precisely reflect the shape of a multidimensional distribution for a collection of chosen ancillary variables. To fulfill the scientific requirement of replicability in metrics, an unbiased estimate with the lowest errors is desirable.

Decision Trees

Decision trees are machine learning, data mining, and rule induction algorithms that categorize data by inferring the interconnectivity between a dependent variable and a set of predictors. Decision trees 1) handle non-parametric data where the predictors are not characterized as having a specific distribution; 2) are insensitive to missing data, to inclusion of irrelevant predictors or to the presence of outliers; 3) effectively operate using numerical, ordinal, binary, and categorical classes; and 4) identify complex hierarchical relationships between predictors and response variables.^[9] Decision trees consist of nodes and leaves with each node representing an *if-then* statement.^[10] The classification tree provides a categorical outcome, whereas the regression tree provides a continuous numerical outcome.

Random Forest (RF) is an ensemble of the Classification and Regression Tree algorithm and operates by aggregating multiple trees to enhance the model accuracy.^[11] RF has the advantage of incorporating “randomness” into its predictions through iterative bootstrap sampling and is less susceptible to overfitting.^[9] Comparatively, “bagging” aggregates the results of many trees, and boosting considers errors from previous classifier steps when sampling data for the next iteration.

Geostatistical Analyses

Geostatistical methods are based on the Tobler’s law and predict unsampled values at point locations from observations at neighboring positions, under the assumption that the values at different locations are spatially

autocorrelated.^[8] Tobler’s law states that observations or measurements close to each other are more likely to be similar than those farther apart.^[12] Examples of geostatistical methods include local spatial averaging, inverse distance weighing, and kriging. The local spatial average computes the value of unsampled locations from the mean of neighboring values; the problem being to define this local neighborhood. Comparatively, the inverse distance weighting computes the values for unsampled locations as the weighted mean of neighboring values, with the weights decreasing linearly from the prediction location, with the problem here being how to deal with the distances close to zero? In kriging, the linear model is fitted by ordinary least squares, and then, a variogram is estimated for the residuals. Cokriging is the multivariate modification of kriging that combines a sparsely measured primary variable (or target variable) with a denser set of ancillary data considered as secondary variable (e.g., remote sensing data) to enhance accuracy.^[13] The limitation of geostatistics is the requirement of dense point data sets.

Remote Sensing

Remote sensing is the science of gathering information by recording sensed or emitted energy from the earth’s surface without physical contact. Remote sensing provides spatially continuous spectral digital data useful for modeling earth system processes and downstream science applications. However, remotely sensed data can be expensive to collect, analyze, archive, and maintain. Furthermore, remote sensors measure only surrogate variables such as reflectance, brightness temperature, and backscatter, from which earth information can be gleaned.

The diffuse reflectance spectroscopy (DRS) visible (Vis) (400–780 nm) and near-infrared reflectance (NIR) (780–2500 nm) are non-destructive, fast, precise, inexpensive, proximal remote sensing tools useful for mapping soil properties.^[14] Practically, models are generated that relate soil spectra, from the Vis and NIR wavelengths with laboratory-based measurements of soil properties. The DRS has been utilized to estimate cation exchange capacity, base saturation, pH, exchangeable bases, and extractable phosphorus, clay content, extractable iron (Fe), total elements such as calcium, magnesium, Fe, manganese, potassium, and copper.^[15] The challenge remains to spatially interpolate spectra of these soil properties across a spatial domain, a feat that may be attainable by classifying soil spectra.

Soil classification for mapping can be done digitally by 1) grouping data/observations that present homogeneous attributes without prior knowledge (unsupervised) or 2) training a model to provide maps based on known soil type observations (i.e., supervised). In the same vein, feature selection and separability algorithms can

be used to separate relevant features from those that are irrelevant. Spectral mixture analyses decompose spectra within pixels based on proportional cover of each pure class, or end-member, enhancing clarity of map products. Unfortunately, the full range of spectral, spatial, and temporal properties for detailed soil classification is difficult to ascertain.

Time series analyses or temporal mapping with satellite imagery can be used for monitoring. Inherent monitoring challenges, such as data gaps from atmospheric scattering, cloud-covered, or shadowed pixels, can be eliminated by normalization. Normalization algorithms identify and merge the pseudo-invariant (i.e., temporally unchanged) features on both the ground and imagery. Mapping soil characteristics remotely may require sensors that generate signals that penetrate obstacles (e.g., vegetative cover, roads, and soil depths) or algorithms that consider these variables.

ASSESSING INTERPOLATION EFFICACY

A key challenge when interpreting maps is quantifying the accuracy and explanatory power of the information. Soil mapping errors can be attributed to the spatial heterogeneity in soil properties and the equipment errors. Accuracy can be assessed by comparing predicted with observed values. For example, a sample data set can be randomly split into 70% for model calibration and development and 30% for validation. Metrics such as the coefficient of determination (R^2), mean error (ME), and root mean square error (RMSE) can be used, with a high R^2 or smallest RMSE or ME indicating higher accuracy. For classified remotely sensed products, the error matrix or contingency table is computed, with the overall accuracy being the ratio of the correctly classified pixels (the sum of diagonal number of pixels in the *matrix*) to the total number of classified pixels, whereas the kappa index being the probability of a pixel classified by chance.

CONCLUSION

This entry provides a synopsis of issues to consider during soil quality interpolation especially under diverse land management scenarios. For comparability and monitoring purposes, fusing data from diverse sources to produce a synthesized indicator of soil quality would suffice. However, because one field can have several soil types, a limitation is the inherent scalar uncertainty when continuously mapping or predicting soil quality. Because interpolation approaches are data driven, interpretations should be done cautiously with local expert knowledge to avoid making

false assumptions, but the major challenge remains how to define the spatial dimensions (e.g., depth) for detailed analyses and interpretation of soil quality.

Abstract

Several gases are either produced or consumed by biological and chemical transformations of carbon (C) and nitrogen (N) in soils. Some of these gases, including carbon dioxide, methane, and nitrous oxide, play a role in the earth's radiation balance (greenhouse effect) while others, such as carbon monoxide, ammonia, and nitrogen oxides (NO_x, i.e., NO and NO₂), have negative impacts on atmospheric chemistry. In this entry, we briefly describe how C and N gases are produced or consumed in soils and how soil management and soil quality can affect these processes.

CARBON (C) GASES

C is the major constituent of biomass and soil organic matter. However, more than 99% of global C is locked into sediments and fossil forms and is not available for biological processes. The small remaining active fraction of global C transits between atmospheric carbon dioxide (CO₂), biomass and soil organic matter, and detritus in the so-called C cycle (Fig. 1). The C cycle is driven by photosynthetic fixation of atmospheric CO₂ by plants. In global terrestrial ecosystems, it is estimated that plant photosynthesis fixes more than 200 Gt of CO₂ every year.^[1] Eventually, similar amounts are returned to the atmosphere by the respiration of animals and by the aerobic heterotrophic decomposition of soil organic matter and plant litter. In the absence of oxygen and other electron acceptors, methane (CH₄) is the final product of soil organic matter decomposition. Human activities, including changes in land use and soil management, are contributing to unprecedented rapid increases in atmospheric CO₂ and CH₄ concentrations, which may result in important modifications of the earth's climate. In dry soils, auto-oxidation of organic compounds can produce carbon monoxide (CO). CO can also be biologically oxidized to CO₂ in moist but well-aerated soils.

Carbon Dioxide

Soil-surface-emitted CO₂, or soil respiration, is the sum of the CO₂ produced by root respiration and heterotrophic

decomposition of root exudates, soil organic matter, and plant litter. Decomposition processes, while dominated by soil microbes, are the result of complex interactions between soil fauna, fungi, actinomycetes, and bacteria. During decomposition, complex molecules such as cellulose, hemicellulose, proteins, and lignin are broken down into low molecular weight substances and oxidized to CO₂ to produce energy and C for the growth of organisms.^[2,3] The rate of decomposition is regulated by the quality and quantity of organic substrates and by physical/environmental properties of soil, such as temperature, moisture, and aeration.^[4]

When ecosystems are in equilibrium, soil CO₂ emissions are the result of the natural recycling of nutrients and equal the amount of atmospheric CO₂ fixed by plant photosynthesis. However, in the past years, human activity has broken this equilibrium by burning fossil C reserves and by decreasing soil organic matter through land use changes. During this period, the additional CO₂ that entered the C cycle could not be completely absorbed by increases in autotrophic activity and atmospheric CO₂ concentrations increased from 280 to 365 ppm.

Several measures have been identified to reduce net CO₂ emissions from soils. Among them, it is believed that modifications in agricultural and forest management practices could result in increased C storage in soils as organic matter. Converting cultivated land into natural ecosystems usually increases soil C content because of increased return of plant litter and decreased

Fig. 1 The soil C cycle. In well-aerated soils, decomposition of soil organic matter produces CO_2 . Significant amounts of CH_4 are produced only under highly anaerobic (waterlogged) soils.

decomposition. Also, tillage breaks down aggregates and increases soil C losses by exposing organic matter to microbes that decompose it. Therefore, reducing tillage intensity, fallow frequency, and the amount of cultivated land (by increasing productivity) and increasing perennial crops in rotation and permanent grasslands are seen as potential management practices for mitigating global warming.^[5]

Methane

CH_4 is produced in soils by the decomposition of organic matter and by the reduction of CO_2 under highly anaerobic environments. Such conditions are found in wetlands and in rice paddies that, together with landfills, contribute about half of the total emissions of anthropogenic CH_4 . CH_4 is stable in waterlogged soils and can be emitted to the atmosphere via diffusion, ebullition, and transport through plants. In the presence of oxygen, certain bacteria can oxidize CH_4 to CO_2 (Fig. 1).^[6]

Human intervention can greatly influence CH_4 production or consumption in soils. Flooding of soils in natural or agricultural ecosystems usually results in increased emissions,^[7] while drainage of wetlands can turn a source of CH_4 into a sink.^[8] Flooded rice fields are a major source of anthropogenic CH_4 . Management practices have been proposed to reduce CH_4 emissions from rice paddies, including draining the fields during the growing season, replacing urea by other types of N fertilizers, and reducing the input of crop residues by using new cultivars and alternative cultural practices.^[5] Reduced rates of CH_4 oxidation in well-aerated soils have been observed following the cultivation and addition of N fertilizers.^[9]

Fig. 2 Schematic representation of the N cycle depicted as a “loop-within-a-loop.” The outer loop traces the passage of N from the atmosphere through ecosystems and back to the atmosphere, while the inner loop traces the interconversion of N between organic and inorganic forms within the soil–plant system.

N GASES

The passage of N through ecosystems can be represented as a “loop-within-a-loop” (Fig. 2). N enters ecosystems primarily through biotic or abiotic processes that “fix” [convert molecular nitrogen (N_2) to biologically available forms] N_2 from the atmosphere. Within the soil–plant system, N undergoes a complex series of transformations, resulting in a continual transfer of N between inorganic and organic forms—the inner loop (Fig. 2). Nitrous oxide (N_2O) and nitrogen oxides (NO_x) are both produced and consumed during these transformations. With time, most of the N entering ecosystems returns to the atmosphere as N_2 , but an important fraction is emitted as gaseous ammonia (NH_3), NO_x , and N_2O . More than 70% of the estimated 18 Tg N_2O –N entering the atmosphere each year is emitted by soils.^[1,10] Above plant canopy emissions of NO_x from soils are probably in the range of 3.3–21 Tg N yr^{−1}.^[11,12] This exchange of N between the atmosphere and the soil–plant system—the outer loop—strongly mediates atmospheric concentrations of NH_3 , NO_x , and N_2O .

Nitric Oxide (NO) and NO_x

The majority of soil-emitted NO_x is NO ,^[13] therefore, the rest of this discussion will focus on N gases other than nitrogen dioxide (NO_2). Nitric oxide is derived primarily via autotrophic nitrification,^[14,15] whereas N_2O emissions can be a product of autotrophic nitrification,^[15] denitrification,^[16] or a combination of both.^[14] N_2O , and particularly NO, may also be emitted from various chemical reactions collectively known as chemodenitrification.^[17]

The magnitude of N_2O and NO emissions is strongly influenced by site-specific variables—most particularly soil attributes—and human intervention. Given that both gases are produced primarily during microbial transformations of inorganic N, the potential of a soil to produce and emit N_2O or NO increases with increasing N availability.^[18] Anthropogenic activities that increase the flow of N into the system also increase the emissions of N_2O and NO . Such activities include, e.g., the cultivation of legume grain or forage crops^[19] and intensive use of N fertilizers.^[20]

Total N_2O emissions tend to increase as soil organic carbon (SOC) content increases. This is understandable, since N turnover is closely tied to SOC turnover, and the amount of C available to drive microbial processes is directly related to the quantity and quality of SOC. The relative availability of C and N is of particular importance when livestock manure or sewage sludge is added to soils. The addition of both C and N tends to increase N_2O and NO emissions more than N alone, particularly in C-limited systems.^[21,22]

Agricultural management practices that minimize soil disturbance tend to increase soil water status and soil bulk density, favoring the development of anaerobic conditions and higher N_2O ^[4] but possibly lower NO emissions.^[23] Conversely, equal or lower emissions of N_2O have also been reported in no-tillage systems compared to conventional tillage systems.^[24] In this instance, reduced soil disturbance appeared to alter N cycling, resulting in lower nitrate (NO_3^-) availability—hence lower N_2O emissions—during the spring thaw period.

In general, soil conditions or management that leads to accumulations of ammonium (NH_4^+), NO_3^- , and particularly NO_2^- favor gaseous N losses. This may happen if N is released during soil C mineralization at a time when plant uptake is absent or minimal, an example being bare soil fallow periods commonly employed in the semiarid regions of North America, or if fertilizer or organic N is added at a time when crop growth is not vigorous. Low soil pH levels (< 5) inhibit NO_2^- oxidizers more than NH_4^+ oxidizers, resulting in accumulations of NO_2^- and abiotic production of NO .^[25] The latter may occur even in near-neutral soils as a result of very high concentrations of NH_4^+ localized in urine patches, or concentrated in bands or nests of NH_4^+ -based fertilizers.^[26]

Ammonia

The production of NH_3 in soils is closely linked to the accumulation of NH_4^+ resulting from the mineralization of organic matter (ammonification) by soil microbes. In agricultural soils, the NH_4^+ content is enhanced where inorganic N and livestock manure fertilizers are used. In soil solution, NH_4^+ dissociates and forms an equilibrium with NH_3 , which can volatilize to the soil air and

eventually reach the atmosphere (Eq. 1). NH_4^+ is also bound to negative exchange sites on soil organic matter and clay minerals (exchangeable NH_4^+) and can be “fixed” within clays. The latter is released slower than exchangeable NH_4^+ .^[27] NH_4^+ is converted through biological oxidation (nitrification) by soil bacteria (nitrifiers) to NO_3^- , which is taken up by plants. Atmospheric NH_3 and NH_4^+ can be recycled back to the soil through dry and wet deposition (Fig. 2).

The volatilized NH_3 from soil is not only a loss of valuable N for crop growth^[28] but also a significant source of atmospheric NH_3 ,^[29,30] which can damage plants^[31,32] and contribute to odor nuisances that are associated with the application of manure to soils. In the atmosphere, NH_3 neutralizes atmospheric acids, and the resulting aerosols contribute to atmospheric haze. Atmospheric NH_3 can also cause acidification of ecosystems by augmenting the capture of sulfur dioxide in clouds^[33] and through nitrification of deposited NH_4^+ and NH_3 .^[34]

Most management techniques that relate to minimizing NH_3 emissions pertain to managing inorganic and livestock manure fertilizers, which are the most significant sources of this gas.^[30,35] The key to these techniques is to reduce exposure of the amendment to the atmosphere either by limiting the amount applied or by the injection/incorporation of the amendment. Manipulating the chemistry of the soil can also be used to control NH_3 emissions especially in amended soils.^[36,37] For example, the addition of acids to fertilized soils can potentially reduce NH_3 emissions. Adding heavy metals or organic compounds with urea fertilizer can inhibit the conversion of urea to NH_4^+ by retarding urease enzyme activity. There is also the potential of adding Ca or Mg salts with urea fertilizers to reduce NH_3 emissions.

Meteorological and soil conditions also modify the emission of NH_3 . Application of manure when soil moisture is initially high but subject to rapid drying can result in higher emission than the normal emissions of NH_3 .^[36,38] High soil moisture content would put more NH_4^+ into solution near the soil surface and increase volatilization. However, irrigation or rainfall following application can leach near-surface NH_4^+ and decrease volatilization.

CONCLUSION

Soil quality and C and N gas dynamics are closely linked. In general, high-quality soils have high nutrient availability and aeration, good infiltration and retention of water,

and a stable structure, all of which are factors that control the production and consumption of gases in soils. Improving soil quality through higher SOC content or better soil structure often results in a reduction of net emissions of greenhouse gases into the atmosphere. Also, soil degradation increases the emissions of greenhouse gases as a result of greater use of N fertilizers, erosion, denitrification, deforestation, and grassland cultivation.^[39] Therefore, adoption of most management practices aimed at improving soil quality also help to improve atmospheric quality.

Quality: Critical Limits and Standardization

Martin R. Carter

Agriculture and Agri-Food Canada, Charlottetown, Prince Edward Island, Canada

Abstract

Critical (“threshold,” “trigger,” “baseline,” “reference”) limits in soil quality assessment refer to the specific value or range of a soil property or indicator that is required to ensure that a soil process or function is not restricted or adversely influenced. Based on the primary concept of “fitness for use” for soil quality, critical limits denote the boundary values or margins of tolerance required for soil indicators that are associated with optimum soil functioning and indicate if a soil is “fit” for a specific use. Standardization refers to the technical protocol for the sampling, storage, analysis, and interpretation of soil properties, attributes, and indicators as a means to provide reliable and comparable methodology for soil quality assessment.

INTRODUCTION

Concerns with soil degradation and sustainable soil management in agroecosystems have emphasized the need to define and evaluate soil and land quality.^[1–3] The basic idea of “fitness for use” in regard to agricultural and/or industrial use of soil, reflected in early attempts to classify “soil suitability” or “land capability,”^[4,5] is the basic premise of soil quality. Ecological concepts, such as function, processes, attributes, and indicators, provide a useful and logical framework to describe and evaluate soil quality.^[4] The framework is based on the following sequence: purpose, function, processes, properties/attributes (including critical values), indicators, and methods (including standardization; [Table 1](#)). The selection of suitable attributes and indicators, the establishment of critical limits for these attributes and standardization related to the protocol and methodology for attribute characterization are key aspects of soil quality evaluation.

CRITICAL LIMITS FOR SOIL QUALITY

A large range of attributes, such as chemical, physical, and biological properties, can be used to describe soil quality. A group of key soil properties/attributes or indicators is called a minimum data set (MDS).^[1,4,5]

Concept of Critical Limits

The concept of “critical values” (also called “threshold,” “trigger,” “baseline,” or “reference” values) is commonly used in soil pollution studies^[6] and is analogous to the “degrees of limitation” for rating land qualities in land use requirements.^[3] Critical limits are needed for each soil quality property/attribute or indicator, within a MDS, so that the measured value of the property can be classed as “optimum”

or “limited” for the specific land use and to ensure that dependent soil processes and function are not restricted or adversely affected.^[1] If the value obtained for the selected indicator falls outside the desired range this would raise questions about the fitness of the soil for the specific use and/or indicate the need for improved management.^[1]

Selecting Critical Soil Properties and Parameters

Past studies have noted the general relation between soil–land use and soil properties resulting in the development of land capability classes and soil productivity ratings.^[1,4,5] For example, the Canadian Land Suitability Rating System categorizes land into classes based on the limitations (e.g., climate, soil, and landscape restrictions) to productivity of a specific crop. The USDA Land Capability Classes based on the rating (eight classes) of six limitations/hazards (e.g., soil erosion, wetness, depth, salinity, sodicity, and climate) provide a meaningful assessment of soil productivity applicable to a wide range of soil types and agricultural crops.^[5] In other examples, a MDS of selected soil attributes (e.g., soil nutrient availability, organic matter, particle size, plant available water, structure, strength, rooting depth, pH, and salinity) is considered adequate to quantify and monitor soil quality.^[1]

Setting Critical Limits

The selection of critical soil properties is followed by the setting of critical limits, or ranges, that help characterize the value of the property as “optimum” or “limited.” If information on critical values is limited, qualitative reference values can be selected based on soil resource inventories or general consensus.^[1,5] An index can then be derived using scores (e.g., 0–1) for the value of each property, along with weighting values for the considered importance or

Table 1 Sequential framework to evaluate soil quality for specific purpose or fitness of use.

Sequence steps	Sequential framework	Questions implied by the framework
1	Purpose	What will the soil be used for?
2	Functions	What specific role is being asked of the soil?
3	Processes	What key soil processes support each function?
4	Properties/attributes	What are the critical soil properties for each process? What are their critical values or range?
5	Indicators/surrogates/pedotransfer functiona	When the soil property/attribute is difficult to measure or not available, what indirect or related property or properties can be used in its place?
6	Methodology/standardization	What methods are available to measure the attribute? Technical rules and protocols for soil sampling, handling, storage, analysis, and interpretation of data.

^aA pedotransfer function is a mathematical function that relates a soil property to another soil property.

Source: Adapted from Larson & Pierce^[1] and Carter & Gregorich.^[4]

priority of each property for soil quality.^[1] The combination of the scores for a group of selected properties provides a quantitative index as an overall measure of soil quality.^[5]

General Classes of Critical Limits

For many soil properties, a quantitative range of values (e.g., low, optimum, high) can be derived based on empirically derived relations between the property and soil processes or some aspect of soil function (e.g., plant growth). These values have general application to a wide range of situations. For example, soil hydraulic conductivity,^[7] macroporosity and aeration,^[8] bulk density,^[9] strength or penetration resistance,^[10] and the least limiting water range^[11] have been characterized on the basis of their

Table 3 Critical level or range of soil physical attributes or indicators for optimum root growth of irrigated fruit trees in duplex soils in southeastern Australia.

Soil quality attribute	Indicator	Critical level
Soil volume	Soil depth	500 mm
Soil strength	Penetrometer resistance	<0.5 MPa
Soil water parameters	Macropores (>30 μm diameters)	>15%
Storage pores (30–0.2 μm diameters)		>20%
Unsaturated hydraulic conductivity (–100 kPa)		>10 ^{–4} m day ^{–1}
Soil aeration	Air-filled porosity (after 24-hour drainage)	>15%
Soil temperature		18–25°C

Source: Adapted from Cockroft & Olsson.^[14]

critical range for plant root development and growth (Table 2). Critical levels and ranges are also available for soil oxygen content,^[10] salinity, and sodicity.^[7] Examples of desirable values are available for plant nutrients, soil pH, and soil rooting depth.^[1]

For soil properties that are multifunctional in nature (e.g., organic matter), the setting of critical limits can be problematic. Some studies have linked critical values of total soil organic matter for specific processes involved with soil fertility and erodibility,^[12] while others have attempted to link or elucidate cause–effect mechanisms between soil functions and soil organic matter and between soil microbiological indicators and macrofauna.^[13]

Site Specific Critical Limits

Although general classes or optimum ranges can be established for many soil attributes in soil quality assessment, it is recognized that the critical ranges must be determined and/or adapted and related to specific land use situations. Generally, critical values for soil attributes and indicators would be site or soil specific. For example, a high clay content may be favoured in a semiarid region, where soil

Table 2 Critical ranges for specific soil properties in relation to root and plant growth applicable over a range of soil types and conditions.

Range	Hydraulic conductivity (m s^{-1})	Macropores (>60 μm diameter; % soil volume)	Relative bulk density (%)	Penetration resistance (MPa)	Least limiting water range ($\text{m}^3 \text{m}^{-3}$)
Limiting (low)	<10–7	<5	<80	<0.5	<0.10
Optimum	10–7–10–4	10–20	82–87	0.5–2.0	0.10–0.20
Limiting (high)	>10–4	>25	>90	>2.5	—

Notes: The low range for hydraulic conductivity and macropore volume and high range for relative bulk density and penetration resistance are generally associated with compact soil conditions that inhibit root growth, while the contrasting limiting range is related to poor root-to-soil contact and poor retention of water. A limiting high range does not apply for least limiting water range.

Table 4 Critical level for soil and associated non-soil indicators, based on improvements relative to community average, used to evaluate resource conservation and sustainability for rice culture on sloping land at Gubu, near Cebu City, Philippines.

Indicator	Critical level (relative to community average)
Crop yield	More than 20% of average yield
Profit	Better than 20% of community average
Frequency of crop failure	Average frequency or 20%, whichever is lower
Soil depth	Average of similar soil types or 50 cm
Soil organic carbon	Average of community or 10 g kg ⁻¹ , whichever is higher
Permanent ground cover	Average of community or 15%, whichever is higher

Source: Adapted from Gomez, Swete Kelly, et al.^[15]

moisture retention is an advantage but may be undesirable in humid conditions in which poor internal drainage may limit yields. In similar fashion, a certain soil bulk density can be optimal under a semiarid moisture regime but deleterious under a humid moisture regime due to changes in relative saturation and subsequent poor soil aeration.^[4] Table 3 provides an example of critical limits for some soil physical attributes selected for irrigated tree crops in Alfisols with a texture contrast in the A and B horizon in southeastern Australia.^[14] Other farm-based studies have developed critical limits for indicators to evaluate farmer satisfaction and resource conservation. Table 4 shows critical limits set for rice (*Oryza sativa* L.) culture in the Philippines based on consensus values at the farm level.^[15]

STANDARDIZATION

Once an attribute has been identified for a specific soil type or situation, information is needed in regard to soil quality standards for a given set of conditions. Soil quality standards are required to ensure that soil sampling, description, and analysis can set the limits for a quality soil and detect adverse changes in soil quality. Usually the critical soil attribute is related to a specific methodology.^[1,4] Standardization deals with the development and applications of technical rules, specification and protocols in regard to a measuring method.^[6] The International Organization for Standardization has developed various standards for soil quality measurements that address the different phases (e.g., soil sampling, handling, storage, analysis) involved in soil characterization.^[6,16]

Quality: Erosion

Craig Ditzler

National Leader for Soil Classification and Standards, Lincoln, Nebraska, U.S.A.

Abstract

Soil erosion involves the detachment and removal of soil material from one site and its transport to another location. Soil erosion usually degrades soil quality and a soil of poorer quality is less able to withstand further erosion, thus creating a downward spiral of soil degradation. When the surface soil is removed through erosion, organic matter and clay particles may be lost, with consequent reductions in fertility, biological activity, aggregation, and rooting depth. Other potential effects of erosion on soil quality include reduced porosity and infiltration, formation of crusts on the soil surface, changes in soil texture, and compaction. These changes in turn reduce the capacity of the soil to supply and cycle nutrients, filter and degrade toxic materials, store and supply moisture, and sustain plant and biological productivity. They may also result in increased runoff, less biomass production and plant cover, and greater susceptibility to further erosion. Erosion increases the variability in soil quality across a field and, on a broad scale, is associated with widespread loss of agricultural productivity and declining water quality.

INTRODUCTION

Soil erosion is a natural process by which soil particles are detached and moved by water, wind, gravity, or ice. All soils have an inherent erodibility, or natural susceptibility to erosion, based on soil features, topography, and climate. However, human activities, such as logging, livestock grazing, tillage, removal of vegetation, and urban development, can greatly accelerate natural rates of erosion. Cleared and managed as they are for crop and livestock production, agricultural soils are particularly susceptible to wind and water erosion (Figs. 1 and 2), and also to a recognized process known as tillage erosion—the loosening of soil by tillage equipment and its downslope movement under gravity.^[1]

Eroded soil may move only a few meters in a field and come to rest in lower positions, resulting in increased variability of surface soil properties across the field as subsoil becomes exposed in some places and surface layers are buried and over-thickened in others. It may also move great distances, being deposited in neighboring fields, roadside ditches, and water bodies. In some cases of wind erosion, fine soil particles may travel many kilometers before being deposited.

EFFECTS OF SOIL EROSION ON SOIL QUALITY

The loss of surface soil in a landscape may impair soil function, and thus soil quality, through adverse effects on many physical, chemical, and biological properties of the

soil.^[2] [Table 1](#) summarizes some of the effects of erosion on the soil quality functions listed by Gregorich.

Physical Effects

Erosion selectively removes the finer, lighter particles from the soil surface, leaving coarser particles behind. Depending on the severity of erosion, an eroded soil may become very coarse in texture, sometimes with a gravelly surface. The deposition of the eroded material in lower topographic areas may result in a thickening of the topsoil and an increase in rooting volume.

Tillage of eroded soils may result in a mixing of subsoil with the surface soil, altering its composition. For example, cultivation of eroded soils having clay-enriched subsoils may increase the clay content of the surface soil. As erosion progresses, plant roots must enter progressively deeper into the subsoil layer to obtain nutrients and water. Where subsoil layers restrict root growth because of their physical and/or chemical properties, the depth of rooting is reduced, along with the capacity of the soil to supply water and nutrients to plants.

Individual soil particles are held together in aggregates, which form the structural fabric of the soil. Soils with good structural arrangement of aggregates and the pore spaces between them provide good aeration for soil roots and microbes; allow ready movement and storage of water and plant nutrients in the pore spaces; and retain their structure when exposed to stresses such as cultivation and the impact of raindrops.^[3,4] Abrasion by wind, rain, and tillage can disintegrate aggregates at the soil surface, and the resulting

Fig. 1 Deposition of wind-blown soil material.
Source: From USDA, Natural Resources Conservation Service—Soil Quality Institute.

fine particles can plug larger soil pores and form a hard, thin crust on the surface. This crust seals the surface and limits the infiltration of air and water, as well as impedes the emergence of seedlings. Finer soil particles are also more easily compacted as the pore spaces between them are reduced under the pressure of farm machinery. Deteriorating soil structure further increases the risk of soil erosion—fine soil particles created by the breakdown of aggregates at the soil surface are especially vulnerable to wind and water erosion. Furthermore, compacted, crusted soils resist the infiltration of water, increasing the volume of surface runoff and compounding the effects of erosion. Thus, erosion reduces soil quality, making the soil prone to further erosion and further degradation.

Chemical Effects

Organic matter and clay are important sites of cation exchange in the soil. Cation-exchange capacity is a measure

Fig. 2 Severe erosion by water has removed all of the surface layer and much of the subsoil.
Source: From USDA, Natural Resources Conservation Service—Soil Quality Institute.

Table 1 Some general effects of soil erosion on soil-quality functions.

Erosion effects	Soil-quality functions affected
Reduced cation-exchange capacity	Sustaining plant growth and animal life Buffering or filtering Regulating energy
Formation of surface crusts	Regulating water, gases, and energy Sustaining plant growth and animal life
Changes in rooting volume	Sustaining plant growth and animal life
Changes in surface layer texture	Sustaining plant growth and animal life Regulating water and gases
Loss of organic matter	Sustaining plant growth and animal life Regulating energy
Compaction	Regulating water and gases Sustaining plant growth and animal life
Deterioration of soil structure	Regulating water and gases Sustaining plant growth and animal life
Exposure of subsoil material	Sustaining plant growth and animal life Regulating water, gases, and energy

of negatively charged sites on the soil particles that are capable of holding positively charged ions, including many plant nutrients. As organic matter and clay particles are lost from the soil surface through erosion, attached nutrients are relocated in the landscape, often to adjacent water bodies where they contribute to declining water quality. Loss of these fine soil particles also impairs the ability to store nutrients, reducing soil fertility. This effect is more pronounced in sandy soils containing small amounts of clay, although it may be offset to some degree if erosion causes the surface layer to become more clayey. Where subsoils are more enriched in clay than the surface soil, the clay particles may form chemical bonds with phosphorus, fixing it into forms not easily available to plants and thus reducing fertility.

For some acid soils with subsoil pH <5.0, concentrations of available aluminum may be at levels toxic to plant roots and removal of surface soil by erosion can effectively reduce the rooting depth of the soil.

Subsoil layers having pH >8.5 often contain high levels of sodium. Surface soil removal and subsequent exposure of these subsoils to rainwater or irrigation waters with low ionic concentrations can lead to dispersion of clay particles, loss of soil structure, surface sealing, and greatly reduced water infiltration.

Biological Effects

Removal of organic matter and nutrients from the soil surface by erosion reduces the food and energy supply needed to sustain healthy populations of soil organisms and support plant growth. Soil organisms are the agents of organic matter decomposition and nutrient cycling in soil.

In addition, they play an important role in the stabilization of soil aggregates through the production of binding agents such as roots, fungal hyphae, polysaccharides, gums, and complex molecules consisting of humic substances combined with iron, aluminum, or aluminosilicates.^[5,6] So, as erosion proceeds, the food source for organisms is reduced, leading to declines in populations. Soil structure and stability then deteriorate, the soil becomes more susceptible to further erosion, and the cycle continues.

CONCLUSION

The interaction of accelerated soil erosion and soil quality is complex. Soil erosion usually reduces soil quality, and a soil of poorer quality is less able to withstand erosion, thus creating a downward spiral of soil degradation. However, many soil-conservation practices have been useful in mitigating the effects of erosion. Reduced tillage systems limit soil disturbance and build soil structure. Crop residue management, underseeding, cover cropping, and permanent cover (e.g., pasture) protect the soil from the action of wind and water. Contour cultivation, grassed waterways, and terracing alter the flow of surface water, curbing water erosion. Herbaceous wind barriers and woody windbreaks and shelterbelts help to control wind erosion. Nevertheless, large tracts of agricultural land throughout the world are subject to the unsustainable loss of soil as a result of erosion

and continued adoption of preventive methods are needed to protect and restore soil quality.

Quality: Indicators

Graham P. Sparling

Landcare Research, Hamilton, New Zealand

Abstract

This entry presents criteria to select soil properties for soil quality indicators. A minimum data set to measure soil quality will include key dynamic properties of the soil quality aspect being monitored, with regard to the spatial scale, and the time span. An interpretative framework is needed to link indicator response to management action. Interpretation will differ according to the soil and land use, and monitoring trends through time is useful where critical limits have not been defined. Multiple indicators can be combined to form a simple index, but in so doing, some soil quality information may be masked.

CRITERIA FOR SELECTING SOIL QUALITY INDICATORS

Many soil properties and characteristics have been proposed as indicators of soil quality.^[1,2] In order to be considered as a valuable indicator, a soil property must meet certain criteria: 1) it needs to get our attention; and 2) it needs to tell us something useful about the condition of the soil. Desirable attributes include being quantitative and responsive within the specified time scale; interpretable; cost effective; scientifically justifiable; socially acceptable; internationally recognized; and preferably a part of historical monitoring procedures.^[1–4]

There is some overlap between the categories of soil quality and land quality, of which soil quality is a subset.^[2,5] Indicators for land quality generally describe the inherent and intrinsic characteristics of the soil, usually on a landscape scale. Inherent characteristics, such as soil mineralogy and texture, soil depth, and stoniness, are used to assess land capability or suitability for use, and generally are not greatly affected by land management. Other inherent characteristics, such as slope and aspect, overlap with soil quality indicators because they influence the more rapidly changing and dynamic soil properties that are responsive to land management. The variety of proposed indicators reflects the many ways in which soil quality has been defined^[5] and the many components of a soil's chemical, physical, and biological attributes that contribute to its overall character. Of its many definitions, quality can be most briefly described as “fitness for use.”^[1,5] Within a soil context, a quality rating depends on how well the soil characteristics match the suitability for a particular use. (See the entry *Quality: Critical Limits and Standardization*, p. XXX.) Soil characteristics are not fixed—what is good soil quality for one land use may be deemed poor soil quality for another use. Thus, quality ratings are not absolute but are instead values based on

interpretation depending on the intended use of the soil.^[6] The soil itself does not change, only our perception of it in relation to human needs.

A Minimum Data Set

Because it is not feasible to measure all soil quality characteristics, indicators need to be selected to address the issues of greatest concern. There are three major categories of soil quality concerns: soil erosion and redistribution; chemical and biological contamination; and soil degradation and depletion. The examples of these categories given in [Table 1](#) are of concern because they adversely influence the role of the soil in ecosystem functioning and services.^[5] Their degree of importance varies in different parts of the world.

Time and Spatial Aspects

Selected indicators must be appropriate to the scale being considered, within both spatial and time dimensions. We tend to classify these items based on human perceptions, and soil processes that geologists consider rapid may be considered slow or relatively static to soil biologists. Examples of time and spatial scales and some relevant soil quality characteristics are shown in [Table 2](#). Human-induced changes to soil, including soil redistribution through erosion and deposition, organic matter depletion, and chemical and radioactive contamination, can take hundreds of years to remediate.

Interpretation

An interpretative framework is needed to make sense of the numeric values obtained for the various soil characteristics. We need to know what constitutes a high or low value, and what target value is desirable for each

Table 1 Major aspects of soil quality requiring indicators.

Soil quality aspect	Examples
Erosion and deposition	Soil redistribution by wind and water, mass movement, slips and slumps, and tillage displacement
Contamination/pollution	Presence of potentially toxic chemicals Pathogenic organisms
Degradation/depletion	Depletion of soil organic matter Loss of fertility Soil acidification Salinization Structural degradation

particular soil and land use. An interpretive framework should also indicate whether there might be off-site consequences for the wider ecosystem. For example, soluble fertilizer contents in soil may benefit crop production

(good quality), but not matching the fertilizer to plant needs may result in an excess, increasing the risk of contaminating receiving waters (poor quality). In general, interpretative frameworks are better defined for contaminants than for other soil quality measures, because the presence of a contaminant can be related to an increased risk to plant and animal health. A critical value can be defined based on toxicity. Such dose–response curves are not available for most indicators used for soil loss, deposition, or soil depletion, and in many cases the response curve is an ill-defined continuum rather than a critical point.^[2] Much work needs to be done to define justifiable targets for soil properties, and even the broad categories of “more is better,” “less is better,” or “optimum range” have been the subject of detailed discussion.^[7] The units of expression can also influence interpretation—expression on a volume or area basis is generally preferred, particularly for comparisons between soils and land uses with differing bulk densities.^[8]

Table 2 Spatial and time scales of soil properties important for soil quality.

Spatial scale	Time scale	Soil properties showing change	Soil quality aspects
Rapidly changing, highly dynamic characteristics			
1–100 mm	Minutes and hours	Moisture content and temperature	Moisture and warmth for plant growth and biological activity
100 mm–1 m	Hours and days	Infiltration and drainage	Compaction due to treading or wheeled traffic, risk of run-off during rainfall, waterlogging in poorly draining soils, poor root environment
		Biological activity	Decomposition of fresh organic matter
Intermediate characteristics			
1 m–100 m	Days and months	Available nutrients and mineralization	Nutrient depletion and supply, nutrient imbalances for plant growth
		Soil structure	Soil damage from compaction; influence on root environment, aeration, moisture retention, and drainage
100 m–1 km	1–5 years	Organic matter content	Turnover of moderately decomposable organic matter, nutrient supply
		Salinity	Saline water in root zone, toxic stress
		Acidification	Soil chemical process leading to acidification in root zone, nutrient imbalances, toxicity
		Erosion and redistribution	Loss of topsoil, soil deposition
Slowly changing characteristics			
1–10 km	5–25 years	Soil loss and formation	Loss of topsoil and decrease in soil depth, soil deposition
		Humus formation or loss	Changes in soil structure and nutrient storage due to loss of organic matter
		Salinity	Salinity in the root zone, toxic stress, rising water tables
		Acidification	Increasing acidity due to leaching and cation/anion imbalance, toxic stress
		`Weathering	Nutrient release and soil formation from rapidly weathering minerals
10–100 km	25–100 years	Stable organic matter	Humus provides exchange sites to retain ions in soil and contributes to soil aggregate formation
>100 km	>100 years	Soil formation	Nutrient release and soil formation from slowly weathering minerals
		Mineralogy	Proportions of sand, silt, and clay, exchange characteristics of the clays

Trends

In the absence of defined critical values for soil quality indicators, the importance of the trend over time has been emphasized.^[9] Trends away from a target range are interpreted as a decline in soil quality; trends toward the target are interpreted as improved soil quality. However, it can also be argued that short-term trends away from a target value could be regarded as sustainable, provided the trend can be reversed within an acceptable time frame. Within the present context, recovery or restoration within a human generation of 20–25 years could be regarded as preserving intergenerational equity.^[10] Such exploitation–recovery cycles were much used during the shifting agriculture phase of human development. Soils differ in their resistance to change, and the rates at which they recover^[11,12] affects their soil quality rating. Generally, soils that are resistant to change, or do change but show a rapid rate of recovery, are regarded as having better quality.^[11]

Combining Indicators

Because multiple data sets are difficult to comprehend, it has been proposed that indicator sets be combined into a single index.^[1,2] These single indices are usually additive or multiplicative combinations of the individual indicators, and a weighting factor is used to adjust for the relative importance of each factor.^[13] While a single number is easier to remember and communicate, its use has the disadvantage of possibly masking information. When too many indicators are combined, poor-quality soil aspects may be masked by those of modest or good quality. Reporting on any soil environmental quality should reflect the limiting quality rather than the average value. For example, excellent chemical fertility is of little use if the physical structure of the soil is badly degraded. This poor physical structure would therefore dominate the soil characteristics.

CONCLUSION

Indicators must attract attention and inform. They need to be sufficiently sensitive for their intended task and to respond in a timely manner. Critical values can be set so that a particular indicator value will trigger a management response. The critical values will differ, depending on the soil and land use, and management options. The ability of soils to recover, and their susceptibility to change under use, will define which indicators are useful and where their critical limits may be set. Multiple indicators can be combined into a single index, using weighting factors to adjust for the relative importance of each indicator.

When combining indicators, care is needed not to mask poor indicator scores, and a safer option is to identify which soil characteristics are limiting factors

Quality: Productivity

Mike H. Beare

Canterbury Agricultural and Science Centre, New Zealand Institute for Crop and Food Research, Christchurch, New Zealand

Abstract

The capacity to nurture and sustain plant and animal productivity is a key function of high quality soils. Indicators of soil quality reflect the key properties and processes that support this function and can be used to assess the fitness of soils for production. In addition to extrinsic factors (e.g., climate), productivity is influenced by both the intrinsic characteristics of a soil (i.e., inherent soil quality) and those processes or properties that are affected by its use and management (i.e., dynamic soil quality). Sustainable production depends on selecting land uses that are well suited to the capability of the soil (and wider environment) and maintaining soil conditions that minimize the risk of productivity declines. The soil quality conditions (e.g., indicator optimum ranges) required to sustain agricultural productivity may be different from, and perhaps less stringent than, those needed to ensure environmental, economic, or social sustainability.

PRODUCTIVITY INDICATORS

Plant productivity depends directly or indirectly on a soil's ability to carry out a variety of functions.^[1,2] The fitness of soil to carry out these functions within acceptable boundaries is the basis of soil quality assessment. Soil quality indicators that can characterize this fitness are useful in assessing plant productivity. For example, a soil's ability to accommodate unrestricted plant emergence and root growth and to permit the effective infiltration and supply of air, water, and nutrients may be described by physical indicators of soil quality.^[3] Chemical indicators of soil quality for plant productivity include properties associated with plant nutrition (e.g., nutrient availability and soil acidity) and properties that reflect an inhibitory or toxic effect on plant growth (e.g., presence of pesticide residues). Soil also supports a diverse community of organisms that both affect and are affected by its chemical and physical properties. Some biological indicators of soil quality reflect a risk to plant productivity (e.g., fungal pathogens), whereas others indicate a potential to enhance plant growth (e.g., plant growth-promoting bacteria). There has been much interest in using biological indicators to describe a soil's capacity to regulate or maintain important soil physical or chemical properties.^[4] For example, the soil microbial biomass may be used as a biological indicator because it reflects a pool of potentially available nutrients (i.e., chemical function) or the ability of soil to maintain soil organic matter levels (i.e., chemical function) or soil structural stability (i.e., physical function).

Animal productivity depends to a significant extent on plant productivity. However, many other factors influence animal productivity, some of which are determined directly

or indirectly by soil quality. These factors include forage nutrient content (e.g., selenium) and quality (e.g., protein content), chemical contaminants (e.g., dichlorodiphenyltrichloroethane), and soil-borne diseases (e.g., parasites). This discussion focuses on soil quality for plant productivity though many of the concepts also apply to animal productivity.

INHERENT SOIL QUALITY

Characteristics that define a soil's inherent capacity for plant production are usually static, changing little over relatively short time frames (years to decades).^[1] They are the product of soil formation driven by climate, topography, parent material, vegetation, and time. Soil mineralogy and particle size distribution are commonly included as properties of inherent soil quality for productivity.^[1] Other attributes, such as total soil carbon, cation exchange capacity, and sodicity, may be defined as inherent properties, where broad soil type or regional comparisons are of interest at one point in time even though they may be altered by management over longer time frames (e.g., decades to centuries).

Inherent soil properties are the basis of many land use capability or suitability assessments^[5,6] that are key components of land use planning and policy development in many regions of the world. Most were undertaken with the primary aim of evaluating potential soil productivity.^[7,8] These assessments are usually developed around a broad set of "land quality" criteria that integrate extrinsic factors (e.g., climate, topography, and hydrology) affecting the composition and productivity of plant communities in an

area with the inherent attributes of the soil. The interplay between these extrinsic factors and inherent soil quality determines the suitability of a land area for a particular agricultural use (e.g., arable cropping, extensive pastoral farming, and forestry).

Thus, the inherent quality of a soil should be viewed in light of its intended agricultural use. For example, in warm humid climatic zones, free-draining, stony soils may be judged as low quality for arable cropping but of high quality for viticultural production. Similar, but subtler, differences in inherent soil quality have been applied to the selection of specific crops, cultivars, or rotations. The Canadian Land Suitability Rating System,^[9] e.g., categorizes land into suitability classes based on the degree to which its environment limits the productivity of specific crops. Suitability classes are indexed from ratings that reflect limitations to productivity posed by climate (e.g., moisture and temperature), soil (e.g., topsoil depth and drainage), and landscape (e.g., slope and stoniness) factors.

DYNAMIC SOIL QUALITY

Soils of high inherent quality for a specific use may not necessarily function within their optimum range (i.e., exhibit maximum potential plant productivity) because of past use and management. This aspect of soil quality is determined by the dynamic properties of a soil.

Properties of dynamic soil quality are those that change in response to human use and management,^[1] normally over relatively short time frames (years to decades). Agricultural soils of high dynamic quality maintain high nutrient availability, permit adequate infiltration of air and water, have a relatively stable structure, and maintain a functionally diverse community of soil organisms that support relatively high levels of plant productivity. These processes are reflected in the specific physical, chemical, and biological properties of soils. The soil properties of greatest importance to productivity in a particular agricultural system are often grouped into a minimum data set^[3,5] defined by identifying the primary issues of soil management (e.g., nutrient deficiencies, risk to compaction, and water storage) that influence crop production on the soils and in the production systems in which they are to be used.^[10]

The terms “dynamic soil quality” and “soil health” are often used interchangeably.^[1] Two soils may be equally “healthy” but achieve different levels of plant productivity because of differences in their inherent quality. In terms of productivity, the optimum range or critical limit of a soil quality indicator is usually defined by applying established criteria to empirically derived relationships between the soil property and some measure of productivity (e.g., annual crop yield and root biomass at crop maturity; Fig. 1).^[10,11] Critical limits for productivity have been established for a number of soil physical and chemical properties. In many cases, as in the example given (Fig. 1), the criteria used in

Fig. 1 (A) A relationship between soil structural condition and relative crop yield used to define the indicator's critical limit. (B) An example of how the critical limit for soil structural condition has been used to improve soil management decisions on the Canterbury Plains, New Zealand.

Source: From Beare, Williams, et al.^[10]

defining critical limits are based on the objectives of the user (e.g., yield targets and profit margins). Where relationships between individual properties and productivity are less clear, some studies have succeeded in indexing data from several different soil properties (minimum data set) into a single value that explains much more of the variation in productivity.^[12] While this approach has some advantages where complex interactions between factors may affect productivity, a single value can also mask information that is important to identify and manage the limitations to productivity.

Many factors influence the level of crop production in any 1 year (e.g., climatic conditions, cultivars, disease incidence, fertilizer rates, and timing). For this reason, the relationship between dynamic properties (or indicators) of soil quality and crop productivity is often difficult to define at a field scale. Where the relationship is known, the loss of dynamic soil quality is probably best described as a risk

to crop productivity. In this respect, the management of dynamic soil quality is often aimed at lowering the risk of productivity loss.

SOIL QUALITY AND SUSTAINABLE PRODUCTION

The use of soil quality information to evaluate the sustainability of soil management systems has involved two common approaches.^[3] With the *comparative assessment* approach, the performance of a system is determined in relation to alternative systems using one-off measures of soil properties. This approach is often used to evaluate potential impacts of land use change. With the *dynamic assessment* approach, the performance of a management system is assessed by measuring the changes in soil properties over time. For example, Fig. 2 shows the nutritive [nitrogen (N) and phosphorus (P)] benefits of different organic amendments (e.g., cattle manure, composted manure, barley straw, and pea hay) for restoring the productivity (wheat yield) of a desurfaced (artificially eroded) cropping soil in Southern Alberta, Canada.^[14] In this example, 87% of the restored yield could be attributed to N and P in the organic amendments, while 13% was attributed to soil structural improvements.

In agricultural systems, the applications of dynamic assessment approach usually involve both monitoring (i.e., repeated measurement) and control (i.e., regulation or management), and the focus shifts from describing soil conditions to maintaining soil conditions that sustain high productivity through improved management (Fig. 1). To this end, soil quality monitoring may be coupled with best management practice recommendations to develop soil

Fig. 2 Effects of total N and P concentrations in organic amendments on the restoration of wheat yields of a desurfaced (artificially eroded) cropping soil in Southern Alberta, Canada. Restoration of crop yields is expressed as a percentage of the non-desurfaced (uneroded topsoil) control.

Source: Adapted from Haynes, Swift, et al.^[13]

management decision support systems that improve the sustainability of production systems.

Using the dynamic assessment approach, sustainable soil management practices are often defined as those that maintain or improve dynamic soil quality.^[3] However, from the standpoint of productivity alone, this represents a somewhat narrow definition of sustainable management. In the short term, agricultural production often results in a degradation of the ordered complex structures that characterize natural ecosystems in equilibrium.^[15] Sustainable management of soil for crop production may involve practices that approach a new steady state or balance degradative processes by restorative processes over relatively short time frames (Fig. 3). For example, in New Zealand and other regions of the world, farmers practice mixed cropping rotations in which the degradative effects of short-term arable cropping are balanced by the restorative effects of pastoral management under grazing.^[13] Where best management practices are employed, the degradation of soil properties is not usually sufficient to significantly impair crop production (Fig. 3). However, the critical limit (or optimum range) for soil properties (or indicators) that sustain high levels of crop production may be less restrictive than those needed to achieve environmental, economic, or social sustainability. Furthermore, a decline in soil quality can be compensated for by an increase in production inputs (e.g., fertilizer, tillage, and pesticides) that may ultimately lower profitability or result in adverse environmental impacts (e.g., nitrate leaching).

The adoption of specific soil management practices is often driven by practical or economic considerations, rather

Fig. 3 A conceptual illustration of changes in soil quality under different types of management in relation to critical limits for productivity (CL-P) and environmental impacts (CL-E). Three types of mixed-cropping (degradative–restorative) management are shown: (A) intensive (e.g., cereal cropping with conventional tillage followed by grazed pasture); (B) extensive (e.g., cereal cropping with minimum tillage followed by grass seed crops and pasture); and (C) unbalanced (i.e., restorative practices insufficient to offset degradative management).

than the potential benefits of improved soil quality for crop production and the environment. Agricultural profitability is difficult to achieve and sustain without a relatively high productivity, but high productivity does not necessarily ensure environmental, economic, or social sustainability. Nevertheless, there are many documented cases in which soil management practices designed to lower production costs and to reduce environmental impacts have also resulted in improved crop performance and sustained economic performance.

Abstract

Sediments and chemicals originating on farms impair more U.S. waters than any other source. Managing soil quality is an essential part of a strategy to reduce these forms of pollution and the costs they incur. Water quality concerns focus attention on soil functions related to regulating water flow and absorbing, buffering, and transforming chemical flows. Organic matter plays a significant role in a soil's ability to perform these functions and serves as one of several key indicators for measuring soil quality. Indicators, however, are scale dependent, and care must be taken in extending soil quality data—typically collected at the field level—to assess water quality at later temporal and larger physical scales. The use of interdisciplinary approaches to implement soil quality mirrors a trend already seen in the development of the water quality concept: after the technical details of indicator selection, sampling, and interpretation are addressed, disciplinary information is integrated into problem-solving frameworks for use by individuals, communities, municipalities, and nations.

SOILS AND WATER QUALITY

According to a U.S. Environmental Protective Agency report of 1995, the leading source of water pollution in the United States is agriculture (Table 1). Declines in water quality worldwide have also been blamed chiefly on the increases in agricultural inputs and crop productivity that have occurred since the 1950's.^[1,2] As efforts in industrialized countries have succeeded in mitigating municipal/industrial point source pollution, the chemicals and sediments that originate on farms impair more aquatic habitats and drinking water supplies than any other source.

In response, many land managers are becoming increasingly judicious in their use of chemical inputs. In the U.S. Corn Belt between 1982 and 1992, e.g., commercial nitrogen (N) and phosphorus (P) consumption dropped by 3.5% and 21%, respectively.^[3,4] But crop productivity is not simply a function of the amount of chemicals applied—soils differ in their ability to release nutrients, maintain adequate moisture and oxygen levels, and allow deep rooting and other functions related to productivity that determine the need for, and efficiency of, chemical inputs. The same is true of water quality—many soil factors affect water quality in addition to, and in feedback with, chemical applications (Fig. 1). For example, increased soil compaction can result from excessive or poorly timed tillage operations, lowering the rate of water infiltration into the soil and leading to increased overland

flow, soil erosion, and stream channel erosion. These processes carry adsorbed nutrients, pesticides, and salts into surface waters; reduce clarity and aquatic plant photosynthesis; and fill channels and reservoirs, limiting boat passage, water treatment capacity, and hydroelectric capacity. In the United States, off-farm erosion costs were estimated to be \$17 billion annually.^[5] That management practices cause differences in the ability of a soil to maintain or enhance water quality is one of the bases for evaluating soils in terms of their quality. Although soil quality is not limited to agricultural applications, it is most often considered in this context because of agriculture's large impact on water quality.

SOIL FUNCTIONS RELATED TO WATER QUALITY

One approach to soil quality evaluates a soil's ability to perform its essential *functions*. Soil functions specifically related to water quality include the ability to partition and regulate water flow and absorb, buffer, and transform chemical flows.

Partition and Regulate Water Flow

Soils are an important switching station in the global water cycle, partitioning precipitation into overland or infiltrated flow. A soil's water-holding capacity and the rate at which water infiltrates the soil help determine the proportion of

Table 1 Leading sources of pollution of assessed waters in the United States: 1992 and 1993.

Sources	Rivers and streams (10 ³ miles) ^a	Rank	Lakes and reservoirs (10 ³ acres) ^b	Rank	Estuaries (sq mi) ^c	Rank

^aTotal river and stream mileage is 3.5 million miles.^bTotal lake, reservoir, and pond area is 40.8 million acres.^cTotal estuarine water area is 34.4 thousand square miles.^dNot among the top 5 sources.**Source:** From Water Quality and Agriculture: Status, Conditions, and Trends.^[3]**Fig. 1** Changes in soil quality affect water quality.**Source:** From National Academy of Sciences.^[6]

rainfall that flows through the soil matrix, which in turn controls the volume of stream flow and the rate of ground-water recharge.

Absorb, Buffer, and Transform Chemical Flows

In natural settings, soils receive and store inputs of N, P, and organic wastes, transforming them into forms available for plant uptake at rates that rarely exceed plant demand. Losses to surface and groundwaters are minimal. In agriculture, water pollution occurs when these inputs exceed the capacity of a soil/plant system to process them or when the soil itself is transported through erosion. Excess N and P levels in lakes and estuaries are the main causes of eutrophication, depleting oxygen levels for aquatic life.^[1,2] Elevated concentrations of nitrates, pesticides, and other organic compounds in waters pose direct risks to human health, although at such levels, these risks are less than to aquatic ecosystems.^[4]

Fig. 1 highlights the important feedback among productivity, soil quality, and water quality. As soil quality declines, so does productivity, reducing the uptake capacity of the plants and leaving more chemicals exposed to leaching and runoff. Profitability likewise declines as input-use efficiency is diminished. In general, farming profitability and water quality are complementary goals, as both are enhanced by improved input-use efficiency resulting from improved soil quality.^[6–8]

INDICATORS OF SOIL QUALITY RELATED TO WATER QUALITY

As these functions may be maintained or enhanced, research in soil quality has sought to identify the relative importance of management-affected soil indicators on multiple outcomes, the optimal levels of these indicators, and the extent to which these indicators are changed by management.

Selecting Indicators

The relative importance of an indicator depends on the outcome(s) of interest. As an example, Karlen and Stott^[9] selected indicators for erosion based on a sensitivity analysis of a simulation model (Table 2). Weightings were assigned to indicators based on their relative influence on sediment loss, with infiltration rate and aggregate stability emerging as the leading indicators. If runoff and leaching concentrations of N and P had been the outcomes of interest, macronutrient concentrations would have been weighted more heavily than they were for sediment loss.

For soil quality monitoring, selected indicators are evaluated either against themselves in relation to a temporal baseline or against “benchmark” soils. Because

water quality is generally high in natural systems such as forests and prairies, undisturbed soils are often used as benchmarks for managed soils with the same inherent properties.^[10–12]

Influence of Management on Indicators

As Table 2 indicates, maintaining soil cover and good soil physical conditions positively affects water quality. Both are related to organic matter management. On the surface, residues and cover crops protect against erosion by absorbing raindrop and flow energy. Together with roots, these additions become the young soil organic matter (SOM) that plays an important role in stable aggregation.^[13–15] Tillage and cropping regimes that favor organic matter accumulations generally maintain or improve water quality. For example, in data from Wisconsin where surface cover was not significantly different between conventional tillage and no-till, lower erosion in the no-till was associated with the enhancement of SOM-influenced characteristics (Table 3). Because of their contributions to SOM status, animal manures, municipal sludges, and some industrial by-products, if applied properly, can also have a beneficial impact on water quality, especially in the context of alternative disposal methods such as lagoons and landfills.^[16,17] Management strategies to improve SOM status and reduce erosion may nevertheless have other water quality tradeoffs. For example, a complete evaluation of no-till would include its reliance on pesticides compared to alternative weed control strategies such as cover crops.^[17]

SCALES OF SOIL AND WATER QUALITY

The influence of management on soil quality is typically measured at the field scale, yet its influence on water quality is expressed at the landscape or watershed level. The time scales over which practices affect soil and water properties also differ. Efforts to extrapolate soil quality information to larger scales are plagued by the fact that processes are not scale independent.^[18,19]

At larger physical and temporal scales, the connection between soil and water quality has been made indirectly by relating management practices to outcomes.^[20] The Universal Soil Loss Equation (USLE), which was developed and implemented before the soil quality concept was popularized, is the best example of this kind of soil and water management strategy.^[21] The USLE and related models have been used to estimate payments to farmers by U.S. government conservation programs, based in part on the amount of crop residue measured on individual farms. Those models have also provided the basis for efforts to scale up field-based information for use at the watershed level.^[22]

Table 2 Soil quality functions and indicators related to water erosion, based on a sensitivity analysis of an erosion simulation model.

Function	Weight	Indicator			
		Level I	Weight I	Level II	Weight II
Accommodate water entry	0.50	Infiltration rate	1.0	Surface crust	0.20

Note: Weightings reflect relative influence of function or indicator on the next highest level.

Source: From Karlen & Stott.^[9]

The successful experience with the USLE points to opportunities for using spatially explicit models to extrapolate field scale indicators to larger scales. Model sensitivity analysis,^[9] metamodeling techniques,^[23,24] and spatial analyses of watershed land use patterns^[25] will be useful in relating soil quality indicators to desirable outcomes for water quality. Spatial analyses are also likely to increase the number of options for managing water quality. For example, watersheds may contain sinks for excess nutrients such as riparian zones to help mitigate plot-level problems.^[26] Some producers will find the construction of a wetland or riparian buffer strips a more economical way to reduce nutrient loadings in streams than reducing application rates of fertilizers.

DECISION MAKING AND POLICY

Establishing the scientific links between soil quality and water quality will not be enough to affect soil management decisions. In order for soil quality to become a valued decision-making tool, methodologies need to be developed that can estimate the economic or environmental value of marginal improvements in soil quality.^[27] Simulation models will be useful in assessing the dynamic biophysical tradeoffs for a wide range of what-if scenarios and management options relating soil and water quality.^[28] The tradeoffs that result from emphasizing one outcome over another—e.g., productivity over nitrate concentration in an adjacent water body—are difficult to evaluate using

Table 3 Soil quality data from surface soils (0–7.5 cm) in Wisconsin after 12 years of tillage treatments.

Parameter	No-till	Chisel	Moldboard	LSD

traditional cost–benefit analyses. Interdisciplinary efforts to identify human preferences and assign economic value to nature, health, and other elusive human welfare outcomes are being used to bridge this gap.^[29–32]

CONCLUSION

Several decades ago, the concept of water quality itself was unfamiliar and controversial.^[33] Evolving through this same interdisciplinary process, water quality has become the centerpiece, along with air quality, of resource management strategy and policy. The very dependence of water quality on soils ensures that farmers and developers, and individuals and governments, will also need to consider soil quality in making resource-use decisions.

Radiometric Survey

Barry G. Rawlins

British Geological Survey, Nottingham, U.K.

Raphael A. Viscarra Rossel

Bruce E. Butler Laboratory, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australian Capital Territory, Australia

Abstract

Measurement of naturally emitted gamma radiation from soil at the land surface can be very effective to aid mapping of a range of primary soil properties, the creation of soil maps, and radon gas hazard assessment. It is unique among remote, soil sensing systems in that it can provide an estimate of bulk soil properties. Measurements are typically made a short distance above the surface of the earth (proximal sensing) or from an airplane flying at between 60 and 120 m altitude. Radiometric survey data are one of the secondary covariates increasingly used in digital soil mapping.

INTRODUCTION

A central objective of digital soil mapping (DSM) is the development and application of cost-effective methods for the creation of continuous soil property maps at suitable scales to aid soil management and policy-related decision making. The approach to DSM described by McBratney et al.^[1] identifies the need for high-resolution auxiliary, predictor variables for the estimation of soil properties. One of the most promising auxiliary variables is airborne (landscape scale) or proximal (field scale) measurements of natural gamma radiation emitted from the soil from radiometric survey. Research has shown that measurements of gamma radiation can be very effective to aid mapping of a range of primary soil properties, the creation of soil maps, and radon hazard assessment. It is unique among soil sensing systems in that it provides a measure of bulk soil properties—not just its surficial properties—with a depth of penetration between 0 and 50 cm of the solum. It has been used in precision agriculture and for understanding landscape-scale processes such as erosion.

THEORY

The application of radiometric survey requires consideration of the measuring system (the detector) and a range of environmental factors, such as soil moisture, rainfall, vegetation, and other sources of radiation. Gamma rays arise from radioactive decay and can penetrate around 30 cm of earth or rock and hundreds of meters of air. Each photon has an energy that is characteristic of its source isotope; the energy range from geological sources occurs in the range 0.2–3 MeV, which concerns this study here.

Three naturally occurring elements produce gamma radiation of sufficient energy for detection (listed here with their average natural abundance in the solum): potassium (K; 2%), thorium (Th; 8.5 mg kg⁻¹), and uranium (U; 2.7 mg kg⁻¹). The proportion of the radioactive isotope of K (⁴⁰K) is fixed, and so the gamma-ray flux can be used to estimate the total concentration of K present in the soil. In the case of U and Th, their concentrations are estimated from the gamma-ray emissions from their daughter products, which are bismuth-214 and thallium-208.^[2]

BACKGROUND RADIATION AND INTERACTIONS WITH MATTER

In addition to radiation from the ground, there are four other sources of “background” radiation flux measured in airborne surveys within this energy range as follows: atmospheric radon, cosmic background, aircraft background, and fallout from man-made atomic explosions and nuclear accidents (¹³⁷Cs). These background signals must be accounted for in the estimation of soil equivalent concentrations of K, Th, and U. Gamma rays also interact with matter, which decreases the intensity of some or all of sample signal before it is detected. The most significant of these processes is Compton scattering in which a photon loses part of its energy to an electron. This can occur in the source of gamma radiation, between the source and detector, and in the detector itself.

Radiation from the ground is attenuated by material between the source and the detector as well as within the source itself. The thicknesses of three different materials that reduce K gamma-ray energies by half as they pass through it are as follows: air, 102 m; water, 11.8 cm; and

concrete, 5.3 cm. Hence, both survey altitude (typically between 60 and 100 m for airborne surveys and less than 2 m for proximal sensing) and variations in soil moisture content can have a significant impact on gamma signals. This attenuation effect and the removal of the coarser (>2 mm) soil fraction in laboratory-based analyses of K, Th, and U may account for the larger measured concentrations of these elements when compared to estimates from radiometric survey.

AIRBORNE SURVEY

Sodium iodide scintillation crystals, which detect gamma rays, are laid in a fixed wing aircraft (Fig. 1) or helicopter to present a cross-sectional area to photons approaching from below. Flying height and aircraft speed determine the support or footprint over which measurements are made from the ground; the quality of gamma-ray spectrometry improves dramatically as elevation decreases because the reduction of gamma-ray intensity with height is approximately exponential. At 56 m altitude, 75% of the measured radiation is from a width of about 150 m, extending to around 220 m along the flight line.^[3] Typical radiometric surveys measure 256 channels monitoring the following four broad spectral windows: K, Th, U, and total counts (Fig. 2). The window count rates need to be corrected for counts resulting from the other elements and for the height of the detector above the ground, and the final data are expressed as equivalent concentrations.

PROXIMAL SURVEY

Proximal gamma-ray spectrometers can be used for surveying or down a borehole to acquire information on lithology

Fig. 2 Typical gamma-ray spectrum.

and geology. The systems can be mounted on vehicles (see Fig. 3) to attain a much greater coverage. Thallium-activated sodium iodide [NaI(Tl)] crystals are mainly used as detectors in these systems; however, thallium-activated caesium iodide [CsI(Tl)] is also available. NaI(Tl) detectors are hygroscopic; they age and are somewhat fragile, and the response of the photomultiplier tube depends on temperature. CsI(Tl) is not hygroscopic and is more robust, but it is more expensive. Proximal gamma-ray spectrometers use smaller crystal packs than airborne sensors, typically between 3 L and 8 L, and typically measure either 256 or 512 channels that comprise an energy spectrum ranging from 0 to 3 MeV (Fig. 2). As with airborne system, GPS navigation is used. The conventional approach to the acquisition and processing of proximal gamma-ray data is to monitor four broad spectral windows or regions of interest (ROIs) corresponding to K (ROI_K), U (ROI_U), Th (ROI_{Th}), and the total count (ROI_{TC}). ROI_K monitors the 1.460 MeV

Fig. 1 Fixed wing aircraft used for airborne survey.

Fig. 3 Vehicle-mounted proximal sensor system.

gamma rays emitted by ^{40}K , while ROI_{U} and ROI_{Th} monitor gamma-ray emissions of the decay products (in parentheses) from the U (^{214}Bi) and Th (^{208}Tl) decay series.^[2] Only these three naturally occurring elements produce gamma rays of sufficient energy and intensity to be measured by ground and airborne surveys. Their isotopes have sufficiently long half-lives for them to remain relatively abundant in the earth, including its surficial deposits—including soil—from which gamma rays are detected. In addition to the gamma radiation from K, Th, and U and their decay products, isotopes emitting gamma radiation are created by cosmic ray interactions with the earth and its atmosphere; this is referred to as background radiation, which has to be removed from survey observations. For ROI_{U} , the energy of the photopeak is centered on 1.765 MeV, and for ROI_{Th} , it is centered on 2.614 MeV. The ROI_{TC} gives a measure of total radioactivity, and it is the integrated count over the 0.4–2.81 MeV range (Fig. 2). Viscarra Rossel et al.^[4] showed that the entire gamma-ray spectrum (256 energy bands) can be used for the prediction of various soil properties using multivariate calibration techniques.

APPLICATIONS

One of the first soil-related demonstrations of airborne radiometric survey was the airborne estimation and ground-based validation of soil moisture along flight lines based on the greater attenuation of the gamma signal in wetter soil.^[5] The negative correlation between wetter soils with the attenuation of gamma-ray K and larger quantities of soil organic carbon (SOC) was used to explain the utility of airborne gamma-ray K as an effective secondary covariate for mapping SOC across Northern Ireland.^[6]

Fig. 4 The distribution of radiometric K across Northern Ireland. Coordinates are meters of the Irish National Grid.

The value of airborne radiometric survey for the identification of soil parent materials was highlighted by Cook et al.^[7] for highly weathered soil landscapes in Southwest Australia. Rawlins et al.^[8] demonstrated that radiometric K and Th are particularly effective for delineating soil parent material types in the young glaciated terrains of eastern England. Fig. 4 shows the spatial distribution of K from an airborne radiometric survey of Northern Ireland; the parent material map accounts for 68% of the variation in K showing that the bedrock and superficial deposits exert a strong influence on the distribution.

The identification of erosional and depositional features has been aided by the use of radiometric survey in Southeast Australia^[9] and aeolian dusts.^[10] Airborne surveys have also been shown to be effective for assessing terrestrial gamma dose rates in California^[11] and for radon potential mapping in Nova Scotia,^[12] which can be used to assess human health impacts.

Proximal gamma radiometrics has been used to establish relationships between ROI_{K} counts and apparent topsoil dust accumulations, which were identified as containing appreciable feldspar and illite.^[10] Rampant and Abuzar^[13] used ROI counts to identify yield management zones for precision agriculture. Many studies also report considerably better relationships between the ROI data and soil properties than do airborne surveys. Wong and Harper^[14] identified excellent linear relationships between ROI_{K} and available K. Pracilio et al.^[15] showed that there was a significant relationship between $\log \text{ROI}_{\text{Th}}$ and gravel content ($R^2 = 0.63$) at a site in Western Australia. They also identified significant relationships between the $\log \text{ROI}_{\text{TC}}$ and clay content ($R^2 = 0.63$). Taylor et al.^[16] identified similar linear relationships between ROI_{TC} and clay content ($R^2 = 0.71$). These authors also found relationships between ROI_{Th} and ironstone gravel ($R^2 = 0.23$) and between ROI_{K} and total feldspar content ($R^2 = 0.62$). Pracilio et al.^[17] attempted to improve the linear prediction models created by Pracilio et al.^[18] by using regression trees, which combined the $\text{ROI}_{\text{K,U,Th}}$ counts with

topographic data to predict soil properties. The technique improved R^2 values for the predictions of clay content but not for available K. Viscarra Rossel et al.^[4] surveyed two geographically and physiographically different fields in New South Wales, Australia, and collected hyperspectral gamma-ray data consisting of 256 energy bands at more than 20,000 sites in each field. They used bootstrap aggregation with bagging-partial least squares regression (bPLSR; see Viscarra Rossel^[19]) to calibrate the gamma-ray spectra of each field for the predictions of clay, coarse sand, and Fe contents in the 0–15 cm soil layer and pH and coarse sand contents in the 15–50 cm soil layer. The authors showed that proximally sensed gamma-ray spectrometry combined with bPLSR is a useful tool for predicting soil properties in different soil landscapes.

Radionuclides

Philip M. Jardine

Oak Ridge National Laboratory, Oak Ridge, Tennessee, U.S.A.

Abstract

The fate and transport of radionuclides through soil is controlled by coupled hydrologic, geochemical, and microbial processes. A multitude of complex soil processes are tightly linked that can both accelerate and impede the subsurface mobility of radioactive contaminants. Often the extent and magnitude of subsurface biogeochemical reactions is controlled by the spatial and temporal variability in soil hydrologic processes.

INTRODUCTION

Soil, the thin veneer of matter covering the earth's surface and supporting a web of living diversity, is often abused through anthropogenic inputs of toxic waste. The disposal of radioactive waste generated at U.S. Department of Energy (DOE) facilities within the Weapons Complex has historically involved shallow land burial in unsaturated soils and sediments. Disposal methods from the 1940s to the 1980s ranged from unconfined pits and trenches to single- and double-shell buried steel tanks. Most of the below-ground burial strategies were deemed to be temporary (i.e., an average life span of several decades) until suitable technologies were developed to deal with the legacy waste issues. Technologies for retrieving and treating the below-ground radionuclide waste inventories have been slow to evolve and are often cost prohibitive or marginally effective. The scope of DOE's disposal problem is massive, with landfills estimated to contain more than 3 million cubic meters of radioactive and hazardous buried waste; a significant proportion of which migrated into surrounding soils and groundwater. It is estimated that the migration of these waste plumes contaminated over 600 billion gallons of water and 50 million cubic meters of soil.

FATE AND TRANSPORT PROCESSES

Hydrologic Processes

Soil is a complex continuum of pore regions ranging from large macropores at the millimeter scale to small micropores at the sub-micrometer scale. It is the physical properties of the media (e.g., structured or layered), coupled with the duration and intensity of precipitation events that dictates the avenues of water and radionuclide movement through the subsurface. In humid environments where structured media is commonplace, transient storm events invariably result in the preferential migration of water.^[1–8]

Highly conductive voids within the media (e.g., fractures and macropores) carry water around low-permeability, high-porosity matrix blocks or aggregates resulting in water bypass of the latter. In these humid regimes, recharge rates are very high with more than 50% of the infiltrating precipitation resulting in groundwater and surface water recharge. This condition promotes the formation of massive contaminant plumes in the soil since storm flow and groundwater interception with waste trenches is frequent and long-lasting. Even in semiarid environments, where recharge is typically small, subsurface preferential flow is a key mechanism controlling water and solute mobility.^[9,10] Lithologic discontinuities and sediment layering promote perched water tables and unstable wetting fronts that drive both lateral and vertical subsurface preferential flow.

In both humid and semiarid regimes, water that is preferentially flowing through the soil media often remains in intimate contact with the porous matrix, and physical and hydrologic gradients drive the exchange of mass from one pore regime to another. Mass exchange is time-dependent and is often controlled by diffusion to and from the matrix. Thus, a significant inventory of radionuclide waste can reside within the soil matrix. This waste source is hydrologically linked to preferred flow paths which significantly enhances the extent and longevity of subsurface contaminant plumes. This scenario is commonplace at the Oak Ridge National Laboratory, located in eastern Tennessee, U.S.A., where thousands of underground disposal trenches and ponds have contributed to the spread of radionuclides such as ¹³⁷Cs, ⁶⁰Co, ⁹⁰Sr, and ^{235/238}U across tens of kilometers of landscape. Highly concentrated contaminant plumes move through soil and groundwater at time scales of meters per day (Fig. 1), since the soils are highly structured and conducive to rapid preferential flow. However, the soil matrix, which has a high porosity and low permeability, serves as a source/sink for contaminants.^[5,6,11] The preferential movement of water and radionuclides through the subsurface also significantly impacts geochemical and

Fig. 1 Field-scale fate and transport of non-reactive Br^- and reactive $^{57}\text{Co(II)EDTA}^{2-}$ and $^{109}\text{CdEDTA}^{2-}$ in fractured subsurface media at the Oak Ridge National Laboratory. Although transport rates are rapid, geochemical reactions significantly impeded the mobility of the chelated radionuclides as are indicated by their delayed breakthrough.

microbial processes by controlling the extent and rate of various reactions with the solid phase. It imposes kinetic constraints on biogeochemical reactions and limits the surface area of interaction by partially excluding water and mass from the matrix porosity.

Geochemical Processes

Radionuclide fate and transport in soil and sediments is also controlled by interfacial reactions with the soil solid phase. Most soils are a complex mixture of variably charged phyllosilicates, redox reactive iron (Fe)- and manganese (Mn)-oxides, organic matter, and mineral carbonates. Radionuclides interact with these solid phases through coulombic exchange, chemisorption, redox alterations, transformation processes such as polymerization, precipitation/dissolution, and complexation reactions. Both the extent and rate of these processes can be significantly influenced by variations in water content and the degree of pore regime connectivity. To make matters worse, radionuclide waste generated at the United States DOE facilities was often co-disposed with various chelating agents and organic acids. These synthetic organic constituents form highly stable, water-soluble complexes with a wide variety of radionuclides.^[13,14] The presence of the complexing agent significantly alters the geochemical behavior of the disposed contaminants in soils and sediments through increased solubility, accelerated redox reactions, and ionic charge reversal.

The geochemical mechanism controlling the fate and transport of chelated radionuclides has been well characterized in numerous soils and subsurface materials.^[15–23] Typically, Fe(III) and Mn(IV) oxyhydroxides are the dominant subsurface mineral assemblages that catalyze cocontaminant oxidation/reduction and dissociation reactions (Fig. 2). The mineral oxides have repeatedly been shown to catalyze the oxidation of $^{60}\text{Co(II)EDTA}^{2-}$ to $^{60}\text{Co(III)EDTA}^-$,

thereby adversely enhancing the transport and persistence of ^{60}Co in a variety of subsurface environments ranging from aquifer sands to fractured weathered shale saprolites.^[16,18,19,21,23] Further, Fe(III)-oxides have also been shown to effectively dissociate a large number of chelated metal and radionuclide complexes (e.g., $^{60}\text{Co}-$, $^{90}\text{Sr-EDTA}$) through ligand competition.^[16,21–23]

Certain radionuclides such as ^{137}Cs do not form strong bonds with many of the chelating agents and organic acids that were used during decontamination. Nevertheless, these radionuclides still interact aggressively with the soil solid phase. In the case of ^{137}Cs , 2:1 phyllosilicates and micas serve as excellent sorbents since the interlayer spaces of these mineral assemblages strongly attenuate the radionuclide. The migration tendency of ^{137}Cs in soils is often related to colloid mobility of contaminated sediments^[24] or cation competition for surface sites in harsh environments such as those found beneath the Hanford tank farms in western Washington State, U.S.A.^[25]

Microbial Processes

Radionuclides such as ^{60}Co and $^{235/238}\text{U}$ can exist in more than one oxidation state, and their behavior in the environment depends on their oxidation state. For example, U(VI) is soluble and mobile in the environment, whereas U(IV) is much less soluble and relatively immobile. Likewise, the oxidized $^{60}\text{Co(III)EDTA}$ complexes are much more stable and exhibit greater mobility in subsurface environments than the reduced $^{60}\text{Co(II)EDTA}$.^[16,18,19] Subsurface Fe- and Al-oxides can effectively dissociate the Co(II)EDTA complex to Fe(III)EDTA^[21] and Al(III)EDTA,^[17] respectively, and aqueous Co^{2+} is free to participate in sorption or precipitation reactions. Co(III)EDTA, on the other hand, is unaffected by Fe(III)- and Al-oxides. Therefore, the oxidized forms of these radionuclides and metals promote their undesirable enhanced migration through subsurface environments.

Fig. 2 Fate and transport of nonreactive Br^- and reactive $^{57}\text{Co(II)EDTA}^{2-}$ and $^{109}\text{CdEDTA}^{2-}$ in undisturbed soil columns of fractured weathered shale. Geochemical reactions impede the mobility of the chelated radionuclides. Co(II)EDTA^{2-} is oxidized to Co(III)EDTA^- where Mn-oxides serve as the oxidant. Fe-oxides effectively dissociate CdEDTA^{2-} complexes resulting in the formation of free Cd and Fe(III)EDTA^- . A flow interruption technique was employed to quantify the presence of physical and geochemical nonequilibrium processes.

Source: From Mayes, Jardine, et al.^[23]

Numerous metal-reducing bacteria have been isolated that enzymatically reduce toxic metals and radionuclides to stable end products. Microbial reduction of U(VI) to form the sparingly soluble U(IV) has been shown using chemostat experiments for a number of metal-reducing bacteria.^[26,27] Gorby et al.^[28] have also shown that certain metal-reducing bacteria can link the enzymatic reduction of $^{60}\text{Co(III)EDTA}^-$ to support cell growth. Important advances have been made toward implementing field scale microbially mediated metal reduction strategies in oxygen-deficient environments. Several studies have investigated contaminant reduction in the presence of solid-phase material.^[28–29] Gorby et al.^[28] have shown that the metal-reducing bacterium *Shewanella alga* preferentially reduced Co(III)EDTA^- to Co(II)EDTA^{2-} in the presence of Mn-oxides. Likewise, Wielinga et al.^[30] documented the bioreduction of U(VI) by *S. alga* in the presence of various Fe-oxide mineral phases. These authors noted that the rate of U(VI) bioreduction was unaffected in the presence of goethite and only slightly diminished in the presence of poorly crystalline Fe(III)-oxides, where the latter Fe solid phase effectively competed as a terminal electron acceptor. Studies by Brooks et al.^[29] showed the sustained microbial reduction of Co(III)EDTA^- under dynamic flow conditions. The net reduction of the Co(III)EDTA^- dominated the fate and transport of the contaminant even in the presence of strong mineral oxidants such as Mn- and Fe-oxides

that are known to effectively reoxidize Co(II)EDTA^{2-} back to Co(III)EDTA^- .^[16,19,21] The research findings of Brooks et al.^[29] provide new and important information on how to successfully implement a bioreduction strategy at the field scale. Their use of a dynamic flow system with sustained bacterial growth conditions in geochemically reactive media is consistent with contaminant migration scenarios *in situ*.

The studies of Brooks et al.,^[29] however, used uniformly packed media that contained little structure. Undisturbed subsurface soils and geologic material consist of a complex continuum of pore regions ranging from large macropores and fractures at the millimeter scale to small micropores at the sub-micrometer scale. Structured media, common to most subsurface environments throughout the world, accentuates this physical condition that often controls the geochemical and microbial processes affecting solute transport. Redox sensitive radionuclides such as U(VI) , Co(III)EDTA , and Tc(VI) reside within nearly all of the pore structure of the subsurface media, with the greatest concentration of contaminants held within micropores.^[2,3] Bacteria that are capable of reducing these contaminants are too big to reach a large fraction of the micropore regime and are largely restricted to macro- and mesopore domains.^[31,32] Fortunately, the pore structure of the media is hydrologically interconnected, and contaminants move from one pore class to another via hydraulic and concentration

gradients.^[4,6,7] This process is slow, however, and is often the rate-limiting factor governing the success of contaminant bioremediation. Thus, faster-flowing fracture-dominated regimes will most likely be physically more appealing for sustained bioreduction as long as a suitable electron donor can be supplied. In contrast, bioreduction processes in slower-flowing matrix regimes will most likely be limited by rate-dependent mass transfer of contaminants from smaller pores into larger pores.

Certain bacteria are also capable of degrading chelates and thus potentially immobilizing radionuclides *in situ*. The biodegradation of the commonly used aminopolycarboxylate chelates nitrilotriacetic acid (NTA), ethylenediaminetetraacetic acid (EDTA), and diethylenetriaminepentaacetic acid have been studied in soil and sediment systems for many years.^[33,34,35] Research has shown that NTA has the greatest potential for biodegradation in subsurface systems compared with the other aminopolycarboxylates.^[35,36]

Bolton et al.^[37] and Bolton and Girvin^[38] have shown that the bacterial strain *Chelatobacter heintzii* (ATCC 29600) is capable of degrading NTA in the presence of many different toxic metals and radionuclides. Likewise, Payne et al.^[39] and Liu et al.^[40] have deciphered the mechanisms by which certain bacteria degrade radionuclide-EDTA complexes. These studies lend promise to the potential for using bacteria to biodegrade chelates and enhance the geochemical immobilization of radionuclides *in situ*.

CONCLUSION

Radionuclide fate and transport in soils is controlled by coupled time-dependent hydrologic, geochemical, and microbial processes. Hydrologic processes such as preferential flow and matrix diffusion can serve to both accelerate and impede radionuclide migration, respectively. Preferential flow results in hydraulic, physical, and geochemical non-equilibrium conditions since differences in fluid velocities and solute concentrations in different-sized pores create hydraulic and concentration gradients that drive time-dependent inter-region advective and diffusive mass transfer. Thus, in soil systems with a large matrix porosity or a significant quantity of disconnected immobile water, radionuclide migration rates can be greatly retarded due to the slow transfer of mass to actively flowing preferential flow paths. Nevertheless, the prevalence of preferential flow can greatly accelerate the transport of mass in soil systems. Geochemical processes such as sorption, redox alterations, and dissociation reactions can also serve to both accelerate and impede radionuclide migration. Sorption and radionuclide-chelate dissociation reactions almost always result in retarded radionuclide migration rates, whereas oxidation reactions often result in more soluble, and thus more mobile, radionuclide species. Microbial processes can also potentially influence

the fate and transport of radionuclides in soil. Metal-reducing bacteria and chelate degraders can alter the geochemical behavior of redox-sensitive radionuclides which facilitates their immobilization via solid phase sorption and precipitation reactions.
